Once again, the general equations for Vf and Vr and therefore Pf and Pr include Zs, Zl, line length, and line Z0. While one or more of these terms might disappear in special cases or ratios, they all have to appear in any equation of general applicability.

I posted a correction to the formula to properly account for the fact that Vr is a complex quantity.

The corrected expression is Prs=|(Vs/2-Vr)|^2/Rs . Apologies if you missed it. Of course, the V quantities are RMS, it is a bit of a botch of RMS with phase as we often do in thinking... but I see you using the same shorthand in your calcs. Although we are using RMS values, don't overlook that where they add (eg Vf+Vr) you must properly account for the phase.

For your cases:

For the 25+j0 load, Vr=-16.67+j0, so Prs=|50--16.67|^2/50=88.9W.

For the 100+j0 load, Vr=16.67+j0, so Prs=|50-16.67|^2/50=22.2W.

Of course, for a 50+j0 load, Vr=0, so Prs=|50-0|^2/50=50.0W.

As you can see, the first two cases have the same |Vr| (though different phase), the same 'reflected power', and yet Prs is very different.

Consider an extreme case, Zl=1e6, VSWR is extreme, almost infinity, Vref= 50+j0, so Prs=|50-50|^2/50=0.0W. Here, your 'reflected power' is as large as it gets, but the power dissipated in the source is zero.

The notion that reflected power is simply and always absorbed in the real source resistance is quite wrong. Sure you can build special cases where that might happen, but there is more to it. Thinking of the reflected wave as 'reflected power' leads to some of the misconception.

Owen

Thanks Roy.

There may have been some misunderstanding. I thought your challenge was issued in the context of the ideal 50 ohm source that Miguel was using as a test case.

The maths for the ideal 50 ohm source test case is so simple, that it is evident the |Vr|^2/Ro is not simply summed into Rs's dissipation.

Of course, in the general case, the maths is uglier, but since the special case of Rs=Ro=Zo proves the 'reflected power' is not simply dissipated in Rs, it (the general case) must give the same outcome.

Owen

That works for me, as long as the time is at least twice the
propagation
time down the line.

Not correct. See the equations for a directional wattmeter below.

> there is no power flowing in the line.

I agree with this, though a directional wattmeter indicates otherwise. See below.

The above equations are used in a directional wattmeter.

You have made some arithmetic errors below. I have re-arranged your prose a bit to allow correction, then comment.

> well, maybe i missed something... lets look at the voltages:
>
> Vf(t)=3D(100+50*2)/2 =3D 100
> Vr(t)=3D(100-50*2)/2 =3D 0

You made a substitution error here. On the transmission line with a constant DC voltage:

  V(t)=3D100V

I(t)=3D0A

substituting in to
Vf(t)=3D(V(t)+R0*I(t))/2
Vr(t)=3D(V(t)-R0*I(t))/2

yields
Vf(t)=3D50V
Vr(t)=3D50V

and
If(t) =3D 50/50 =3D 1a
Ir(t) =3D 50/50 =3D 1a

Recalling that the definition of forward and reflected is
V(t)=3DVf(t)+Vr(t)
I(t)=3DIf(t)-Ir(t)
we can check our arithmetic
V(t)=3D 50+50 =3D 100V
I(t)=3D 1-1   =3D 0A
Exactly as measured.

If you are disagree with the results, please point out
my error in the definitions, derivations or arithmetic.

If you agree with the results, continue reading.

> so there is a reflected 2a current you say?

Well, with no arithmetic errors it is 1A of forward and
reflected current.

> where does that go when it gets back to the source?
> we know that when the 100v source is open
> circuited as it must be in this case that it develops 100v across its

> the source. it can't be reflected since the source impedance matches
> the line impedance. so where does it go? maybe those simple
> algebraic expressions have to be reconsidered a bit.

Now you see the problem of assigning to much reality to the
these waves.

In principal, the derivation and use of forward and reflected
waves is no different than using superposition to compute the
currents and voltages in simple circuits. Consider

```
                50ohms
     +----------\/\/\/\/---------+
     |                           |
   -----                       -----
    --- 50V                     --- 50V
     |                           |
     +---------------------------+
```

Obviously the current in the resistor is 0, but let us use superposition to solve this problem.

To solve using superposition, one sets all but one of the voltage sources to zero and then computes the currents. Repeat for all voltage sources and sum the results in each element.

So set the right voltage source to zero.
The current through R is 1A.
Set the left voltage source to zero.
The current through R is =961A.
Total current through R is 0A, as expected.

Asking =93where did the reflected current go?=94 on the transmission line case is like asking =93where did the =961A go?=94. The question is nonsensical. The =961A is simply an intermediate result in a method that lets the problem be solved.

The fallacy of assigning powers to the reflected waves also has an analog in the simple circuit above.
Using the currents derived above, compute the power from the left source.
  50*1*1 =3D 50W
and the right source
  50*(-1)*(-1) =3D 50W
So what do your think...
Should we add them to get 100W?
Subtract them to get 0W?
Or is the operation invalid because superposing power just does not work?

Answer 3 is correct.

Taking this knowledge back to transmission lines, the surprise is that subtracting reflected power from forward power actually yields the net energy flowing. How can that be?

By substitution, it is easy to show that the rules used to derive Vf and Vr results in
  P(t)=3DPf(t)-Pr(t)

So, while superposing powers, does not work in general, it does for this case. Directional wattmeters take advantage of this ideosyncracy to let the user compute the power being delivered to the load.

None-the-less, thinking of these waves as transporting energy will lead to much confusion.

...Keith

Ahhh. Your standard answer. You are an RF dude and there is nothing
```

that can possibly be learned from simple DC circuits.
Especially when the results challenge your beliefs.

Still, I observe that you have discovered no errors in the exposition.
Which is good.

We studied DC circuits in EE101. Later we were forced to expand our
knowledge into distributed networks because the DC circuit model
failed at RF frequencies.

> Still, I observe that you have discovered no errors in the exposition.

I have not wasted my time time trying to discover any errors. In a
nutshell, what new knowledge have you presented?

Again, exactly who proposed that notion? The "power" in a reflected wave is actually reflected energy measured at some point on the transmission line. Reflected EM waves cannot exist without ExH energy per unit time per unit area.

The special case where 100% of the reflected power incident from a Z0=3D50 ohm transmission line is dissipated in the 50 ohm source resistor happens when there is zero interference between the forward wave and reflected wave. Since it is not true when interference exists, it is logical to conclude that interference has something to do with the reflected power results deviating from the zero interference case - and so it does. The interference term in the power density equation indicates what kind of interference exists and what happens to the interference energy.

Roy's experiment was designed to eliminate re-reflections from the source and it does exactly that. What that means is that all of the variations in power distribution are associated with interference, the other mechanism by which RF wave energy can be redistributed. Contrary to w7el's assumption, EM wave reflection is NOT the only mechanism for redistributing RF energy in a transmission line. That glaring fact of physics is what most of the RF experts are missing.

> If I do not make any mistake, my numbers agree with yours Cecil, it is
> a pleasure (my procedure was the old plain and simple standard) =A0:>)

If, instead of a voltage analysis, one does an energy analysis, what happens to the reflected energy becomes obvious. I posted an earlier example that nobody solved. So let me repeat it here.

```
------Z01------+------Z02------
```

The power reflection coefficient at point '+' is
rho^2 =3D 0.5. The power transmission coefficient
is (1-rho^2) =3D 0.5
Pfor1 on the Z01 line is 100w
Pref1 on the Z01 line is 0w
What are Pfor2 and Pref2 on the Z02 line?
What is the SWR on the Z02 line?

The power reflected back toward the source at point '+' is

Pfor1(rho^2) =3D 100(0.5) =3D 50w

We know that Pref1 is zero, so

Pref2(1-rho^2) =3D 50w

Since 1-rho^2 is 0.5, Pref2 must be 100w and

Pref2(rho^2) =3D 50w

We also know that Pfor1(1-rho^2) =3D 50w

So we have two 50w waves trying to flow toward the source and two 50w waves trying to flow toward the load. Do we have 100 watts flowing in both directions? No, that would be superposition of power which is a no-no. Using the power density equation indicates what is happening.

Pref1 =3D 0 =3D Pfor1(rho^2) + Pref2(1-rho^2) minus total destructive interference at the Z0-match

Pref1 =3D 50 + 50 - 2*SQRT(50*50) =3D 0

Pfor2 =3D Pfor1(1-rho^2) + Pref2(rho^2) plus total constructive interference

Pfor2 =3D 50 + 50 + 2*SQRT(50*50) =3D 200w

Since Pref2/Pfor2 =3D 0.5, the SWR on the Z02 line is 5.83:1

Note that we have solved the problem without knowing the value of Vfor1, Vfor2, and Vref2. But let's assume Z01 is 50 ohms which makes Z02 equal to 291.5 ohms. Now we can calculate the voltages assuming Vfor1 at '+' is our phase reference:

Vfor1 =3D 70.7 volts at zero degrees at '+'
Vref1 =3D 0
Vfor2 =3D 241.4 volts at zero degrees at '+'
Vref2 =3D 170.7 volts at 180 deg at '+'

Vfor1(rho1) =3D 50v at zero deg
Vref2(tau2) =3D 50v at 180 deg

Vfor1(tau1) =3D 120.7v at zero deg
Vref2(rho2) =3D 120.7v at zero deg

There's the interference, voltage style. Two voltages superpose to zero toward the source while engaged in total destructive interference. What happens to the energy components that are supporting those two voltages? There's only one thing that can happen. They are obviously not flowing in their original directions so they must necessarily flow in the only other direction possible. Total destructive interference toward the source results in total constructive interference toward the load.

Someone earlier remarked about the fact that when two 50w waves combine, the result is one 200w wave. That is total constructive interference in action and that extra energy had to come from somewhere.

I have an old Radio Shack 11 meter 3 element beam that I plan to put on 6 meters. I once did the EZNEC modeling with the boom length being the only constraint. It was possible to come up with a model that would work with a direct match for 50 ohms to the driven element. I hope to try to construct it soon.

The problem with holding a few parameters constant is that you have to
accept whatever gain, patterns and such that come with the deal.

I also have a very old Mosley 15 meter 3 element beam that I want to
modify to 17 meters. I am having a lot of fun with PSK31 there with
poor antenna setup now.

Tower space is a limiting factor in my case and I am not interested in
anything that compromises my A3S!

I wish you were close to me rather than 2306.9 miles, I am looking for
an old bargain tri band to tinker with. There is a lot there I don't
understand!

John Ferrell W8CCW

Well I did find plans for a 6 elem on a 17.5ft boom. The boom on the
old A4S is 18Ft. If I use the parts off my old A3

and my A4 I should be able to come up with all the parts for the 6 element. And its direct connect.

I wonder how far above the A4 the 6 meter needs to be. I only have a 5ft mast.

my DX800 rotor should handle it.

And it works only if Z0 is purely real. When it's not, P(t) also includes Vf*Ir and Vr*If terms which are neither "forward" nor "reverse" power. It's unfortunate in a way that Z0 is close enough to being real for decent lines at Amateur frequencies that these terms are small. Otherwise they'd have to be confronted and some mistaken assumptions abandoned.

While Zo of transmission lines might not be purely real, if the sampler element is calibrated for V/I being real, then the power is given by 'forward power' - 'reflected power'. This is true even if the calibration impedance is different to the transmission line in which the measurements are made, though significant departure will impact measurement uncertainty.

For example, if I insert a 50 ohm Bird 43 in a 75 ohm line at 1.8MHz, and measure Pf=150W and Pr=50W, then the power is 150-50=100W. The insertion VSWR due to the Bird 43 is trivial in this case, so it hardly disturbs the thing being measured. Each of the power measurements is of little value alone, no inference can be made (in this case) of the actual line VSWR, but the difference of the Pf and Pr readings does give the power at that point.

I discuss this in my article entitled "http://vk1od.net/blog/?p=1004" at http://vk1od.net/blog/?p=1004 .

Good day:

> wave as 'reflected power' leads to some of the misconception.

Ugh! The slippery word again...! Please Owen, remember me what power
definition are you using here and expand the sentence idea.

> EM waves cannot exist without ExH energy per unit time per
> unit area.

This is what teachers taught me, but when the EM TL waves reachs a
"target" seems the issue arise in the newsgroup.
Puzzle to me why we can (want? :>)) not reconcile those physics
concepts with usual electricity concepts if today they arise from the
same place ultimately?
Certainly in electromagnetism we deal with vectors E,D,B,H,S and in
electricity with scalars V(t), I(t) or phasors, this is for
convenience and simplicity, but I accept we should be able to
understand them in both forms without contradiction.

Adding a directional wattmeter to the mix raises an interesting issue.

Recalling my earlier example of a 100 watt transmitter connected to a half wavelength 200 ohm transmission line and then to a 50 ohm resistive load, the "forward power" on the line was 156.25 watts and the "reverse power" or "reflected power" 56.25 watts. The subject of this topic asks where the "reflected energy" goes. Does it go back into the transmitter? Well, let's put a 50 ohm directional wattmeter between the transmitter and the line. It measures 100 watts forward and 0 watts reverse. So what happened to the "reverse power" on the transmission line? If it was going back into the transmitter, we've now fixed the problem just by adding the wattmeter. In fact, we could replace the wattmeter with a piece of 50 ohm transmission line of any length, as short or long as we want, and the "forward power" on that line will be 100 watts and "reverse power" zero. So we've protected the transmitter from this horrible, damaging "reverse power" just by adding a couple of inches of 50 ohm line -- or a directional wattmeter. Is this cool or what?

Or we can put the wattmeter at the far end of the line and read 100 watts forward and zero watts reverse, eliminating "reverse power" at the load -- although we've lost 56.25 watts of "forward power". Or put it at the center of the line, where we'd read a whopping 451.6 watts forward and 351.6 reverse(*).

These are the "forward power" and "reverse power" on the short 50 ohm transmission line (or lumped equivalent) inside the wattmeter. So we can create "forward power" and "reverse power" just by moving the wattmeter around. And most importantly, we can use it to isolate the transmitter from that bad "reverse power". What a powerful tool!

I should point out that the example doesn't even mention, or need to mention, the transmitter output impedance. The entire analysis holds for any transmitter impedance, whether "dissipative", "non-dissipative", linear, or nonlinear. Wherever the "forward power" and "reverse power" come from and do to, it doesn't depend on any particular value or kind of transmitter impedance.

(*) This brings up a great idea. Drop down to Radio Shack or HRO and pick up one of those circulator things that separates forward and reverse power. Put it into the middle of the line where you have 451.6 watts of "forward power" and 351.6 watts of "reverse power". Take the 351.6 watts of "reverse power", rectify it, send it to an inverter, and use it to run the transmitter -- you'll have plenty, even with poor efficiency, and you can unplug the transmitter from the mains. There should even be enough power left over to run your cooler and keep a six-pack cold. Then work DX with your 451.6 watts of forward power while you enjoy a cool one. Goodbye to electric bills! Hello to DX, free power, and a tall cool one!

Roy Lewallen, W7EL

except i can measure If and Ir separately and can see they are both
zero.  this is where your argument about putting a resistor between
two batteries falls apart... there is a length of cable with a finite
time delay in the picture here.  so it is possible to actually watch
the waves reflect back and forth and see what really happens.  in the
case where the line is open at the far end we can measure the voltage
at both ends of the line and see the constant 100v, so where is the
voltage difference needed to support the forward and reverse current
waves?  you can't have current without a voltage difference.  plus i
can substitute in a lossy line and measure the line heating and
measure no i^2r loss that would exist if there were currents flowing
in the line, so there are none.

try this case, which is something we do at work... take a 14ga piece
of copper wire maybe 50' above ground, its characteristic impedance is
probably a few hundred ohms, and put 100kv on it... how much power is
it dissipating from your If and Ir heating losses??  lets say 200 ohms
and 100kv gives 100,000/200a=3D500a, shouldn't take long to burn up that
wire should it?  and yet it never does... so why doesn't it have your
circulating currents?

but you have already admitted that it is the only mechanism... though you will now undoubtedly argue against yourself.   em wave reflection IS the only mechanism for redistributing rf energy, you admitted that when you agreed that superposition of the waves is the mechanism that causes the interference in the first place. since interference is caused by superposition then wave cancelation and this so called redistribution of energy is also caused by the superposition of the reflected wave with the incident wave. RF experts are not missing anything, they just don't talk in your fancy energy and power terms all the time or figure how to calculate power superpositions... read the 500 pages BEFORE the s-parameter discussion in your version of the fields and waves book and learn the simple way to handle the single wave components that makes all that stuff you preach look over complicated.

except for the one guy in the other thread that likes his dc 'waves' i
think most everyone else gets the same answers but won't acknowledge
that the other peoples methods also work.  even my simple transformed
impedance method shows the same results, you just have to look at what
it really means.  the whole key is that it doesn't really matter, we
know how to use voltage/current, E/H, powers, s-parameters, etc to
design circuits, and as long as we know their limitations and stay
within them everything should work the same way no matter how its
designed on paper.

news:IomdnUO5naQZCofRnZ2dnUVZ_jSdnZ2d@giganews.com:

> Adding a directional wattmeter to the mix raises an interesting issue.

Roy,

I suspect that the directional wattmeter is in a large part responsible to the strong committment to the view the Pf and Pr are separate tangible quantities, and that they can be dealt with independently.

You will recall a raging argument some years ago about the possible range of rho, and insistence by some practical practitioners that rho could never be greater than unity because it would mean that reflected power was greater than forward power, obviously impossible, then citing experience with a directional wattmeter (calibrated for V/I being purely real) as evidence. Of course, telephony line designers know about this effect and do not have directional wattmeters to confuse their thinking.

You example goes on to point out the absurdity of application of that kind of thinking.

Miguel has asked why I keep quoting the term 'reflected power' etc, it is because it is a deceptive label that misrepresents the quantity.

Roy has explained, and I have explained in the articles I referenced, the assumptions that underly the concept that Pf=Vf*If, and its limitations.

There are many ham texts and articles that try to explain some concepts and deliver to the user a language and model that encourages extension to invalid application.

Miguel, in a steady state scenario with a source at one end of a TEM line and a load at the other, the power (rate of flow of energy) at any point is given by the product of instantaneous voltage and current. This is a time varying quantity which can be integrated over time to obtain the average power. At some points on the line, the instantaneous power may be negative for some parts of the cycle, which indicates that over a cycle, some energy is exchanged to and fro across that point, but the average power will always be from source to load, and that quantity will decrease from source to load as accounted for by line loss elements, though in the general case, not purely exponentially as sometimes believed.

Owen

Superposition and reflection are NOT the same mechanism. You are totally confused about what I have said. Wave REFLECTION (of one wave) is not caused by SUPERPOSITION (of two waves) and vice versa. Wave reflection happens to a single wave when it encounters an impedance discontinuity. Superposition requires two or more waves. They are clearly two completely different mechanisms. So I will repeat what I said before:

There are two mechanisms for redistributing the reflected energy back toward the load.

1. The re-reflection of the SINGLE reflected wave from the load at an impedance discontinuity associated with the power reflection coefficient, e.g. 0.5 in my earlier example. Thus in that earlier example, 1/2 of the reflected energy from the load is re-reflected back toward the load and joins the forward wave toward the load. That leaves 1/2 of the reflected energy that is transmitted through the impedance discontinuity toward the source without being reflected.

The second energy redistribution mechanism occurs associated with superposition of MULTIPLE WAVES.

2. The percentage of the reflected energy from the load that is transmitted through the impedance discontinuity toward the source superposes with the reflection of the source forward wave from the impedance discontinuity. In my earlier example, the following two wavefronts superpose in the direction of the source.

Pfor1(rho^2) =3D 50w and Pref2(1-rho^2) =3D 50w

Pref1 =3D 50w + 50w - 2*SQRT(50w*50w) =3D 0

This is the second mechanism (wave cancellation) that redistributes the energy in the canceled wavefronts back toward the load. This step 2 is technically NOT a reflection since it involves two waves. This is the step that the RF gurus are missing.

I really wish you understood the s-parameter equations which are easier to discuss than the above RF equations.

In the s-parameter equation:

b2 =3D s21*a1 + s22*a2

the term, s22*a2, is the SINGLE WAVE re-reflection term, i.e. a2 is the reflected voltage from the load.

In the other s-parameter equation:

b1 =3D s11*a1 + s12*a2 =3D 0

s11*a1 and s12*a2 are the TWO WAVEFRONTS that superpose to zero, i.e.
engage in wave cancellation.

The subject of this thread is: "Where does it go? (mismatched power)".
So it did matter to the original poster. I have answered the question
by presenting the facts of EM wave physics known from the field of
optics. So now you say, "it doesn't really matter". That seems to be a
final fallback position.

On Jun 17, 4:45=A0pm, Roy Lewallen <w...@eznec.com> wrote:

> Recalling my earlier example of a 100 watt transmitter connected to a half wavelength 200 ohm transmission line and then to a 50 ohm resistive load, the "forward power" on the line was 156.25 watts and the "reverse power" or "reflected power" 56.25 watts. The subject of this topic asks where the "reflected energy" goes. Does it go back into the transmitter?

------Z01=3D50------+------Z02=3D200------load

Pfor1 =3D 100w, Pref1 =3D 0w
Pfor2 =3D 156.25w, Pref2 =3D 56.25w
rho^2 =3D 0.36, rho =3D 0.6

That's obviously a Z0-match to 50 ohms. There are, as usual, four wavefront components:

Pfor1(rho^2) =3D 36w, the amount of forward power on the 50 ohm line that is reflected back toward the source.

Pfor1(1-rho^2) =3D 64w, the amount of forward power on the 50 ohm line that is transmitted through the impedance discontinuity toward the load.

Pref2(rho^2) =3D 20.25w, the amount of reflected power on the 200 ohm line that is re-reflected back toward the load by the impedance discontinuity.

Pref2(1-rho^2) =3D 36w, the amount of reflected power on the 200 ohm line that is transmitted through the impedance discontinuity toward the source.

Pref1 =3D Pfor1(rho^2) + Pref2(1-rho^2) - total destructive interference

Pref1 =3D 36w + 36w - 2*SQRT(36w*36w) =3D 0

Pfor2 =3D Pfor1(1-rho^2) + Pref2(rho^2) + constructive interference

Pfor2 =3D 64w + 20.25w + 2*SQRT(64w*20.25w)

Pfor2 =3D 64w + 20.25w + 72w =3D 156.25w

Note that the 72 watts of total destructive interference energy toward the source has changed directions and joined the forward wave toward the load as constructive interference.

No need to haul out a wattmeter or SWR meter. A pencil, paper, and calculator is all one needs PLUS an understanding of the rules of physics governing energy flow at a Z0-match.

Actually, you didn't even need to tell me what the Pfor2 and Pref2
values are. As you can see from the calculations, they are easy to
calculate even when they are unknown.

How would you measure them? The standard definition of forward
and reflected waves are as I provided above. I suppose you could
construct your own definitions, but such a new definition would
be confusing and unlikely to have the nice properties of the
standard definitions.

> waves? =A0

Well, as I suggested, the forward and reflected wave are somewhat
fictitious. They are very useful as intermediate results in solving
problems but, as you note above, quite problematic if one starts
to assign too much reality to them.

That is why they are quite analogous to the two currents in the two battery example.

> you can't have current without a voltage difference. =A0

You can, though, have an arbitrary current as an intermediate result in solving a problem. With the two battery example, reduce the resistor to 0 and an infinitely large current is computed in both directions, though we know in reality that no current is actually flowing.

> plus i
> can substitute in a lossy line and measure the line heating and
> measure no i^2r loss that would exist if there were currents flowing

I certainly agree that there is no real current flowing, but the fictititious If and Ir are indeed present (or pick a better word if you like).

> circulating currents

I really like this example. I thought of using something similar once to convince Cecil, but never did. He is unreedemable. But your example aptly demonstrates why If and Ir are not real, though still useful because If-Ir is the actual current flowing.

Just as an aside, your comment above about requiring a voltage to cause a current to flow is not quite correct. An ideal conductor has zero resistance, so current can flow without voltage in an ideal conductor. Strangely, this can even be achieved in the real world with superconductors.

So I offer another example for your consideration. The experiment is the same as above (100V, 50 ohm, ideal source and conductors) but this time short the end of the transmission line. After waiting for the line to settle, we find 0 volts everywhere and 2A flowing.
Recalling the coversion equations:
  Vf(t)=3D(V(t)+R0*I(t))/2
  Vr(t)=3D(V(t)-R0*I(t))/2
  If(t)=3DVf(t)/R0
  Ir(t)=3DVr(t)/R0

we obtain:
  Vf(t)=3D(0+100)/2 =3D 50V
  Vr(t)=3D(0-100)/2 =3D -50V
  If(t)=3D1A

```
  Ir(t)=3D-1A
```

Substituting to verify

```
  V(t)=3D50+(-50)=3D0V
  I(t)=3D1-(-1)=3D2A
```

Exactly as measured.

I will caution again, do not assign too much reality to these
forward and reflected waves; very useful for solving problems,
but trouble if carried too far.

...Keith

Quoting "Fields and Waves ...", by Ramo and Whinnery: "A perfect
conductor is usually understood to be a material in which there is no
electric field at any frequency. Maxwell's equations ensure that there
is then also no time-varying magnetic field in the perfect conductor."
How does one go from zero current to a non-zero current if the
magnetic field is prohibited from varying (changing) with time?

I'm afraid you are too late with that advice. Optical physicists have
assigned reality to forward and reflected waves inside an
interferometer and have tracked all of the energy including the energy
in canceled wavefronts.

http://www.teachspin.com/instruments/moderni/experiments.shtml

Scroll down to, "Using Dielectric Beamsplitters to find the "missing
energy" in destructive interference" It says: "... when interference
is destructive at the standard output, it is constructive at the non-
standard output."

In RF terms, when interference is destructive at a Z0-match, it is
constructive in the direction of the load.

Inertia first Newton law applied to the free electron lttle balls
perhaps?
Now, if at first of experiment little balls was at rest, how do they
set in movement without a force? Tell us.
.....
Keith, OM,  if you do not make the rope experiment,  make this another
simple one =3D>  get from Radio Shack a long, long lossles TL, (with
vf=3D1, why not?), 6*10^8 meters long it is good, open or short ended
(it does not matter). Connect it to your 100 W rig, key for a one
second the TX full CW power, inmediately disconnect the TL and touch
the connector with your fingers. Just count: tree, two, one, =A1zero!.
If after "zero" you still with the connector in your fingers without
blink, then reflected waves really have not too much reality... have
some ointment for burns, may be the boys are right.>) (sorry, do not

It would be really really REALLY effing great if you dorks would take
this to a suitable forum. This has nothing to do with antennas.

And it is an unproductive infinite length, in case you bunch have missed
that point. But I'm guessing that given how intelligent you all are,
you already figured that out, and are ignoring it. No one is changing
their position, and they never will.

And yes, I have the thread set to "ignore". Which everyone should.

I will NOT see your responses.

Dear Roy:
This is a brilliant piece of work, it clarify so much misconceptions
(or extension of certain concepts beyond its scope). However the
question of "why" persist floating somehow.
Without leaving conventional approachs I think in the article cited in
the "Where does it go?" thread there are some helpful and valuable
hints: http://www.ittc.ku.edu/~jstiles/622/handouts/Transmission_Lines_pack=
age.pdf

Page 25 =3D> "The precise values of Vo+, Io+ Vo+ and Io- are therefore
determined by satisfying the boundary conditions applied at each end
ofthe transmission line.
Page 28 =3D> Although Vo+- and Io+- are determined by boundary
conditions
(i.e., what=92s connected to either end of the transmission line),
the ratio V+- / V+- is determined by the parameters of the
transmission line only (R, L, G, C).

What it is your opinion about?

Hello Miguel,

The part of the paper you quote is very standard transmission line analysis which can be found in any textbook on the subject -- although I find this treatment to be better written than most. Nothing I have ever posted contradicts, or intends to contradict, the very well known and established theory which has been found to be correct and useful for over a hundred years. What I find silly is the idea that there are waves of average power bouncing back and forth, needing to "go" somewhere, and the specious arguments put forth in desperate attempts to explain where these elusive waves "go" and how they supposedly behave. (But interestingly, people seem much less concerned about where that extra "forward power" comes from.) It's very much like a pseudo-scientific exposition on the nature of ghosts or arguments about the effects of various astrological signs.

As you've hopefully seen from my few recent postings, it's painfully simple to show that most of the conceptions about these power waves are ridiculous. But one can't change someone's religion by means of rational arguments, and it's a fool's errand to try. So my postings aren't directed to the power-wave zealots but rather to the few people who are still open to reason. I see you're one of them, and I'm glad you've giving the topic some careful thought.

Roy Lewallen, W7EL

> This is the second mechanism (wave cancellation) that redistributes

but that is NOT a "second' mechanism. it IS superposition, which is
what you agreed to earlier, maybe in a different thread. the
mechanism is superposition, the observation is that the waves
interfere either constructively or destructively.

> the energy in the canceled wavefronts back toward the load. This step

no we are not, we understand superposition which is the underlying
basic mechanism of your optical interference terms.

>

you edited too much out of context... it doesn't matter which method
you use to calculate where it goes as long as you know the limitations
of your method.

Good day Miguel,

In the example you provide, there would be real energy flowing and
it would be clearly shown by
  P(t)=3DV(t)*I(t)
P(t) will be negative because the energy is flowing in the reverse

direction.

Computing Pf and Pr would reveal
  Pf(t)=3D0
  Pr(t)=3D-P(t)

So Pf(t)-Pr(t) =3D> P(t) as it must.

I see no conflict with anything that I have written previously.

There are many examples where one can observe energy flow in a
reflected wave.

It just takes one counter-example to demonstrate that this is not
always
the case and that one should not assign *too* much reality to such
waves.

What this neans is that when someone asks "what happesn to reflected
energy?", the first question you have to answer is "Is this a
situation
where the computed reflected power represents something real?"
because
if it does not, the original question is moot.

...Keith

you said you had a directional wattmeter, so do i. mine reads zero,
what does yours read?

>The standard definition of forward

fictitious?? i can measure them, watch them flow from here to there,
and see physical effects of them, doesn't sound very fictitious to
me. weren't you the one who teaches tdr use? what are you seeing in
the steps of the tdr if not for reflected waves coming back to your
scope?

>
> That is why they are quite analogous to the two currents in the two

no, that is why they aren't analogous. lumped components can't
represent the traveling waves.

>

no it isn't. in the limit at R->0 0V/R still looks like 0 to me.

>

now you say they are fictitious, yet you have formulas for them and
can measure them... until you come to your senses and admit that
reflections are real there isn't much we can do for you so the rest of
your post is based on an incorrect premise.

Actually, I'm following and enjoying the conversation. Since you set
your computer to ignore responses, then you should have no objection if
they continue. It makes more sense to ignore subjects which don't
interest you than to complain about them.

It's really an electromagnetic wave obeying all the laws of physics
for an electromagnetic wave INCLUDING ENERGY CONTENT. ExH is the power
density of the wave and the voltage coefficient squared is the power
reflection coefficient. All of the power/energy math used on a Z0-
match gives identical answers as using the voltages PLUS it answers
the original question asked by the first poster to this thread about
what happens to reflected energy. The answer is that reflected energy,
like any other energy, is conserved traveling at the speed of light in
the medium, until it is dissipated or radiated.

Try measuring the voltage and current content of a laser beam and you
will realize why optical physicists are decades ahead of RF engineers
in understanding where EM wave energy goes.

> > This [superposition] is the second mechanism (wave cancellation) that r=
edistributes
>
> but that is NOT a "second' mechanism. =A0it IS superposition, which is
> what you agreed to earlier, maybe in a different thread.

In my statement above "This" refers to "superposition" which is the
second mechanism after reflection, the first mechanism. ***I REPEAT!
(1) REFLECTION IS NOT THE SAME AS (2) SUPERPOSITION!!!*** You are now
just engaging in obfuscation of what I have said. I expect such shabby
behavior from others on this newsgroup, but not from you.

Wave cancellation is just a special case of superposition, i.e. wave
cancellation is superposition.

(2nd mechanism) Superposition =3D=3D> Interference =3D=3D> Wave Cancellatio=
n,
which is ***NOT*** the same as
(1st mechanism) Reflection. I cannot say it any plainer than that.

Exactly! The method that most RF engineers use does not tell how the energy flows. Witness the posters who are implying that a reflected wave contains no energy because they cannot figure out where that energy goes or how it gets there. In his food-for-thought example, w7el completely ignores the role of superposition/interference in redistributing the energy, a phenomenon known and understood in the field of optical physics for at least a century.

On the contrary, what you have said indeed does contradict 100 years
of optical physics. All you have to do to alleviate your ignorance is
to grok that superposition (wave-cancellation/interference) can and
does redistribute energy even when there are no reflections present.
The ONLY time that a forward wave and a reflected wave don't interfere
with each other is when they are 90 degrees different in phase.

> What I find silly is the idea that there are waves
> of average power bouncing back and forth, needing to "go" somewhere, and

Have you never stood in a hall of mirrors where the reflections seem
to go on out to infinity on both sides? You would have us believe that
those reflections are not bouncing back and forth, mirror to mirror,
and that those reflections that you can see with your own eyes have
zero energy??? Roy, you are just spouting guru-type metaphysics,  and
should be ashamed of yourself for trying to spread your religion to
the unwashed masses.

Hi,

I'm not sure if this is the right group btw.
I have an archos mp3 recorder with a 20gb hardrive
in it. It has a stereo line in I use to record
talk shows from a grundig radio.

When I record one particular fm station, a static
pulse is heard thru the headphone monitor
output of the archos. This pulse gets recorded
and I want to get rid of it. It is not heard thru
the grundig's speaker however.
No matter where I position
the archos, using a long cable, and no matter
where I position the antenna, this loud
pulse comes through the headphone monitor.
Why does this not come
thru the actual radio, and not other stations,
but only on this one station?

Thanks,

itchy

Sorry and thanks Cecil I do not see this kind answer (I still using
normal Google groups reader and loss tracking of your message).
Tomorrow I will analize it with care, now is late here but I do not
want delay my aknowledge.

Miguel

After I got out of the Navy, I worked as a Marine Electrician, installing equipment on Navy ships. My foreman told me that it is rarely done, but the Navy can perform a Quality Assurance "pull test" of 25 lbs on a connector. I think that's a lot of pull for a connector to withstand.

Yes, if you are looking for a steady state solution, that is a valid solution, and almost the easiest solution.

If you are using lossless lines, then the solution can be simpler than the Telegrapher's Equation which uses hyperbolic trig functions. Simple trig functions suffice if the line is lossless... but of course, the hyperbolic functions will also work.

The reason I said "almost the easiest solution" above is that a trig based simplification of the Telegrapher's Equation is simpler than the hyperbolic Telegrapher's equation.

Implicit in this is that for the steady state, it doesn't matter how an external network dictates V/I (Z) at the source/load terminals, whether or not transmission lines are involved, or their length, the power delivered by the source to its immediate load is determined by Veq, Zeq of the source, and Zl of the load.

If an experiment indicates othewise, the experiment is flawed (eg something is wrong with the assumed values for circuit components, measurement error etc).

Taking Walt's example, he connected three 50 ohms loads in parallel, then attached a nominal 50 ohm line of 13.5� electrical length. If you use TLLC (http://www.vk1od.net/calc/tl/tllc.php) to solve this problem at 4MHz using RG213 (though I don't know what he used), Zin is 17.78+j10.58. A lossless solution will have very slightly lower R. Walt measured 17.98 + j8.77 which suggests that the load at the end of the 50 ohm line was not exactly 16.6667+j0, or the line a little shorter, Zo off spec etc.

Whilst the above focuses on steady state analysis, understand that steady state analysis is not appropriate for some types of transmitters, but for systems where the transmission line propagation delay is small compared the the highest modulating frequency, steady state analysis should be adequate.

Owen

Hi Walt,

For every hundred pundits there is at least one bench worker that is more productive than them all. Of course I am being facetious, it is probably closer to a thousand.

In the SARL Forums at:
http://www.sarl.org.za
search for the 19/04/2009 posting by ZS6BIM with the thread name:
Measuring the Output Impedance of a 100W Class AB HF Linear Amplifier
Plenty of data and charted and screen shots of O'scopes.

A very intriguing use of directional couplers (much as I would expect Tom to have done). It seems to me I've directed you to similar work (the rat-race-like method seems familiar to our email discussion some dozen years ago).

The writer had the cojones to use his vector voltmeter at the transmitter's antenna terminal. Back in 1997 I used my GR bridge to look down the throat of the fire breathing dragon (TS430S) while it was asleep and got similar results:

10 MHz	74 Ohms
14 MHz	74 Ohms
18 MHz	60 Ohms
21 MHz	37 Ohms
25 MHz	35 Ohms
28 MHz	48 Ohms
29 MHz	70 Ohms

33e RADIO FLEA MARKET in BEETSTERZWAAG on 28 May 2011

The radio flea market takes place to - 28 May 2011. Do you look for an exotic transistor kit or a super recipient, fixed and do manufacture kit...
or do meet of radio friends? Dan comes Saturday 30 May to the Friese radio market into Beetsterzwaag!

Many thousand visitors come each year from the entire Netherlands and Europe to this radio flea market spectacle, approx. 100 dealers, with most diverse articles, like transmitters, recievers, power supplies, antennas, software, hardware and literature.

Additionally of businessmen in the place also a flea market with many attraction organized for large and small. There are some sales desks free at the moment on the radio flea market, you can reserve by telephone & email, contact on to take with the executive committee. Down are these addresses.

How does one find after Beetsterzwaag? From direction Apeldoorn = > Zwolle = > Meppel = > Heerenveen = > Drachten, departure after Gorredijk Tijnje comes departure (28) Beetsterzwaag.

From direction Bremen = > Groningen = > Drachten = > Heerenveen, departure after Drachten Haven comes departure (28) Beetsterzwaag.

On 2mtr, 145,700 Digi Heerenveen can one to instruct leave themselves. Inlet is from 09:00 to 16:00 MESZ, into which Cafeteria one also boarded into this time.

This whole is organized of VERON FRIESE WOUDEN. Cordially Welcome in Friesland on the 33e FRM!

Look for more information at the site: www.frm.a63.org

IMO, the error that Bruene made is similar in concept to the some of the errors being made here in this thread. Many people assume that a simple reflection is the only way to change the direction and momentum of an EM wave in a transmission line. In "Reflections", Sec 4.3, Reflection Mechanics of Stub Matching, you describe the role of wave cancellation associated with interference as a mechanism for redistributing reflected energy back toward the load. You said, "Wave interference between these two complimentary waves at the stub point causes a cancellation of energy flow in the direction toward the generator." It seems obvious to me that your "virtual short" reflection at a Z0-match point is a combination of ordinary wave reflection and interference patterns adding up to zero energy flowing toward the source. Obviously, interference can also happen inside a source.

Redistribution of energy can occur associated with destructive/
constructive interference inside the source and has an effect on the V/
I ratios, i.e. on the impedances. Bruene's pinging method completely
ignores the role of interference at the source. The Z =3D (Vfor+Vref)/
(Ifor+Iref) impedance for coherent waves may be a completely different
value than for the non-coherent pinging waves.

Miguel, some posters here don't seem to realize that your questions
involve a source like the one specified by w7el in his foot-for-
thought article. That source may bear little resemblance to an actual
ham transmitter but it is the one w7el specified and it can be easily
analyzed for source resistor dissipation and tracking of the reflected
energy.

> Since we're trying to resolve both resistance and reactance, we need
> to change the load in at least two directions that have a degree of

> orthogonality. =A0But we could also change the load over a range of values. =A0For example, we could connect a 51+j0 load directly to the output port we're trying to measure, and then connect it through varying lengths of 50.0 ohm lossless coax. =A045 electrical degrees of line would shift the phase of the 51 ohm load so it looks instead like 49.99-j0.99 ohms. =A090 electrical degrees shifts the 51 ohm load to 49.02+j0 ohms, and so forth. =A0Measurements of the varying amplitude output with those loads will give us enough information to resolve the source resistance and reactance and open-circuit voltage.
>
> For a 51 ohm load on a 50 ohm line, the reflection coefficient magnitude is 1/100, so if the transmitter is putting out 100Vrms forward, the reverse is 1Vrms.
>
> Now consider a method to change the line length that doesn't use individual sections that have to be patched in and out, but rather uses a "trombone" section that, in theory anyway, could range from zero length to essentially infinite length. =A0Picture that trombone section getting longer at a fixed rate, so now the load is rotating around a circle on the linear reflection coefficient plane (which is, by the way, exactly the same plane the Smith chart is plotted on); the circle is centered at zero and is a constant 1/100 amplitude, with linearly varying phase. =A0So the 1Vrms reverse wave on the line of the 100Vrms forward example arrives back at the amplifier at continuously varying phase. =A0Imagine that the phase shift is 360 degrees in 1/100 of a second. =A0Now note that the reverse wave corresponds _exactly_ to a wave offset in frequency from the forward wave by 100Hz. =A0If the line is continuously lengthening, the offset is negative; if the line is shortening instead, the offset is positive.
>
> Now, from the point of view of the amplifier, can that scenario be distinguished from one in which I have a perfect 50 ohm load that absorbs all the transmitter's output, and a method to introduce a "reverse" 1.00Vrms wave into the line at a frequency that's offset from the transmitter's output by 100Hz?
>
> If you believe that the amplifier can distinguish between those two scenarios, I fear we have nothing more to discuss.
>
> Cheers,
> Tom

Hello Tom,

The method of constant varying phase of a mismatch to determine output impedance I use in my simulation also (because it saves me time). I use a second source with some frequency offset instead of the trombone as you described (the trombone I cannot implement easily in my pspice package).

When you change the phase very slowly, a soft power supply may change voltage during the slow variation (as a load change may result in a DC supply current change). When the difference frequency is sufficiently high (for example 200 Hz or more), the electrolytics will keep the supply voltage constant during all phase "steps". Therefore there may be slight difference between measurement with a set of loads with increasing phase and the RF injection method (for example with vector analyzer).

I checked the injection method in simulation for linear circuits (with both real and complex output impedance), linear active circuits, and power circuits. I couldn=92t find any flaw in the method. So I think your reasoning is valid.

Some results applicable to PAs, inclusive the implementation in simulation are in: http://www.tetech.nl/divers/PA_impedance.pdf. Note that I determine the reflected voltage by means of interference with the amplifier's output signal (envelope detection) as this saves me from making a narrow band filter that results in very long run times.

I am now simulating a circuit with 6146 valve and pi-filter output (50 Ohms) and I will add it to the document.

Best regards,

Wim

I chose that length so that the transmission line would have no effect
on the impedance seen by the transmitter. As I've said many times, and
you've continually disagreed with, increased dissipation and/or damage
at the transmitter is due to the impedance it sees, and not by
"reflected power". The example I gave keeps the transmitter load
impedance constant while changing the "reflected power". And it shows
that neither the transmitter nor the load see any changes in dissipation.

If I had chosen a different length line, then changing its Z0 would have
changed the impedance seen by the transmitter, which would have changed
its efficiency by an amount which could have been determined only with
additional knowledge about its characteristics. But replacing the
transmission line with a lumped impedance transforming network would
have exactly the same effect on the transmitter, again illustrating that
the only important factor is the impedance the transmitter sees and not
the "reflected power" in the line it's connected to.

This posting is being made, though, for the benefit of other readers.
I've explained this many times to you before with no noticeable effect
on your understanding.

Roy Lewallen, W7EL

Thanks, but I've designed TDR systems and prepared and given classes on the topic.

Cecil has used this fact as a convenient way of avoiding confrontation with the illustrations given in my "food for thought" essays. However, those models aren't claimed to be Thevenin equivalents of anything. They are just simple models consisting of an ideal source and a perfect resistance, as used in may circuit analysis textbooks to illustrate basic electrical circuit operation. The dissipation in the resistance is clearly not related to "reflected power", and the reflected power "theories" being promoted here fail to explain the relationship between the dissipation in the resistor and "reflected power". I contend that if an analytical method fails to correctly predict the dissipation in such a simple case, it can't be trusted to predict the dissipation in other cases, and has underlying logical flaws. For all the fluff about photons, optics, non-dissipative sources, and the like, I have yet to see an equation that relates the dissipation in the resistance in one of those painfully simple circuits to the "reflected power" in the transmission line it's connected to.

Thank you, that's exactly what I've tried to do. But calling all such simple circuits "Thevenin equivalents" is a convenient way to avoid having to explain the phenomena they illustrate. So that has been the tactic of some of the "reflected power" proponents.

Sal M. O'Nella wrote:

> After I got out of the Navy, I worked as a Marine Electrician, installing equipment on Navy ships. My foreman told me that it is rarely done, but the Navy can perform a Quality Assurance "pull test" of 25 lbs on a connector. I think that's a lot of pull for a connector to withstand.

In a previous life I was tasked with tailoring a large number of RG-58 cables connecting radar scopes at a new installation in Korea. This involved cutting the cables to length and installing clamp and solder type BNC connectors. The rumor was that the Korean troops were supposed to be helping us, but we never saw them -- until one day, when they showed up. The one assigned to help me sat down and, neither of us being fluent in the other's language, I proceeded to show him how to assemble the connector.

Now the job of one of the several pieces, a metal ring, is to push against and expand a rubber washer, which is mainly what holds the connector together. This piece looks like it should go upside down from the correct orientation, but if put on that way, the rubber washer won't expand and the connector will come off very easily, with only a gentle tug. If assembled correctly, it'll take a lot of pulling, as Sal says, to get it off. I've never seen a correctly assembled connector come off.

Getting back to the story, I carefully demonstrated the correct assembly method to the Korean troop, emphasizing the orientation of the ring. After putting the connector on, I showed him our standard test. We would grab the connector in one hand and about two feet down the cable with the other. Then we put our hands together, making a loop of cable, and briskly yanked them apart, resulting in a really good sharp tug on the connector. A properly assembled connector had no trouble with this test.

So I gave him the parts and went to work on a connector. After a while he handed me the cable with attached connector. I gave it the tug test and the connector snapped right off. So I repeated the mimed instructions, with extra emphasis on the ring orientation, then put him to work again and got back to what I was doing. When he was finished he handed me the connector, I did the yank test, and again the connector popped right off. He shrugged, muttered something under his breath, got up, and left. Guess he figured he'd had enough of that game, where he assembled connectors and I pulled them off. We never saw the Korean troops again.

Another story, but with a different outcome.

I worked in a training school at one stage, and we thought we would get trainees to make up BNC RG58 patch cables as a practical exercise, and we would feed the output into our satellite labs where cables didn't seem to last long (trainees pulled equipment trolleys around by the coax if it didn't reach the desired socket).

Total failure, the BNC field serviceable connectors were just too complicated for dissinterested trainees more interested in discussing fast cars than concentrating on the job... and they had no stake in it, if the cables didn't work, it didn't matter too much.

Solving the problem of the connectors pulling off led me to the Amphenol specs, and I found that the pull out spec for the field serviceable connectors was *much* lower than the spec for the crimp connectors.

So, I bought a quality crimp tool (in those days, it was a few hundred dollars), and some Kings crimp connectors, and we switched the classes to use the crimp components and a trim jig. The outcome was much better, fewer faulty cables, and the crimped cable retention was much better and consistently so.

No I know that one of the large suppliers to hams advertises "crimped, not soldered", but that is just a blatant case of playing to the market. A bit like the single core 4:1 Guanella balun that manufacturers attribute to Sevik's assurance that it will work fine on a fully floating load... whan antenna system is a fully floating load. The theme is the customer is always right, if he wants something that doesn't make sense, see Rule 1.

An interesting new connector type is the "compression connectors", "Snap-n-Seal" is a proprietary name. I tried some of these on RG6, and a bit suspicious of the cable retention mechanism, every one I tested using different types of RG6 (including QS), hung on until the cable tore apart some distance from the connector.

Owen

Got that back the front, didn't I.

DXE advertises "soldered, not crimped", but that is just a blatant case of playing to the market.

Owen

Some of the statements I've seen are based on assumptions that there is a large number of radials, or that the radials are evenly distributed. When either of those aren't true, some of the "conventional wisdom" doesn't apply.

I also need to point out that EZNEC isn't a very good tool for studying some of the effects of abbreviated radial systems.

It is possible to create a small amount of directivity by putting more radials in some directions than others. I'll use as an example an NEC-4 (which allows modeling buried conductors) model I had previously made of a 3.7 MHz quarter wavelength vertical with 60 radials buried in average ground. The radial length is 0.5 wavelength in free space, or about 2.25 wavelengths when buried, since the propagation velocity is much slower in the ground.

With all 60 radials, the maximum sky wave gain is 1.08 dBi at an elevation angle of 26 degrees. If you delete half the radials, the gain is 0.19 dBi at 27 degrees in the direction of the radials, and -1.39 dBi in the opposite direction. So about 1-1/2 dB of directivity has been accomplished, at the expense of about a dB of gain in the best direction.

As far as radiation from radials is concerned, a pair of opposed radials (that is, ones facing opposite directions) radiate very little because their fields nearly or completely cancel in all directions. The example antenna with only two opposing radials shows -3.57 dBi gain at 25 degrees elevation, and 0.3 dB or less deviation from having the same gain in all directions, at any elevation angle.

The same model with only one radial shows a front/back ratio of about 0.8 dB at the elevation angle of maximum gain, and about 1 dB at some higher angles, so even that doesn't give much directivity.

Analyzing antennas having radial systems with EZNEC requires elevating the radials above ground. When many radials are used, the approximation to a buried system isn't too bad, and the main limitation of the model (homogeneous ground) prevents highly accurate results anyway. But a single radial behaves much differently when buried than when elevated even just a little. Elevating the single buried (0.1 meter deep) radial of the previous example to 5 mm above ground results in about 5.6 dB front/back ratio and -7.74 dBi maximum gain vs -4.42 dBi with the radial buried. So if you want to get significant front/back with a single radial, keep it above the surface. Gain varies quite a bit with radial height and length.

EZNEC can be used to see what happens to the pattern and gain as one or more radials are elevated at various heights and made various lengths. The results can be quite surprising. While the homogeneous ground approximation makes it unlikely you'd see results matching a model at a particular height, the general effect of height can prove illuminating.

I saw the challenge and note the lack of response.

Let me offer a steady state solution.

In the case of a simple source being an ideal AC voltage generator of Vs and an ideal series resistance Rs of Ro, and that Zo=Ro, for any arbitrary load, at the source terminals, Vf=Vs/2, Vl=Vf+Vr=Vs/2+Vr, and the voltage difference across Rs is Vs/2-Vr (noting that Vr is a complex quantity and can have a magnitude from 0 to Vs/2 at any phase angle), therfore dissipation in Rs is given by:

Prs=(Vs/2-Vr)^2/Rs where Vs is the o/c source voltage, Vr is the complex reflected wave voltage equivalent, Rs is the source resistance.

Clearly, dissipation in Rs is related to Vr, but it is not simply proportional to the square of Vr as believed by many who lack the basics of linear circuit theory to come to a correct understanding.

Roy, is that a solution?

Owen

obviously its not the 'reflected power'... that can be easily disproved by showing that the length of the line changes the impedance seen at the source terminals without changing the power that was reflected from the load. since it is the impedance at the source terminals that determines the performance of the amp the power that is reflected is irrelevant.

however, it should be relatively easy to derive such a relation for a simple thevenin source with a lossless line and a given load impedance... just transform the impedance along the length of the line back to the source then calculate the resulting current or voltage from the source. that would give you the power dissipated in the source. then you could also calculate the reflection coefficient and separate the forward and reflected waves... and if you did it all correctly and kept everything in terms of RL, Z0, and the length of the line you could come up with a family of parametric curves relating the power dissipated in the source resistance to the reflected power over a range of load impedances for a given line length, or for varying line length for a given load. obviously a purely academic exercise that should be left for a rainy day.

no, i've read enough thank you.

I think there are 2 basic things you are missing... V and I are functions not only of time, but of distance along the line, both for the forward and reflected waves. looking at them at specific points can lead to incorrect assumptions and over simplified conclusions. Also, there are very good reasons why the sinusoidal steady state condition is used to simplify the equations they way they are normally shown, and why your over simplifications won't hack it in the long run. to do the full analysis of a distributed system (except in very special cases) for an arbitrary waveform requires summations of reflections both ways on the line over many reflection periods.. the results of this for step functions can be seen with simple tdr's on lines with multiple discontinuities where you can see the reflections ringing down.

Tom, I understand the variation of the line-input impedance resulting
from the change in length of the trombone line with the reflection
coefficient of 0.01. However, I'm totally unaware of how the change in
line-input impedance relates to a change of frequency of the forward
wave of 100 Hz. Please explain.

Further, will you please also explain how the effect of the trombone exercise determines the value of the source impedance, which, for example, you stated is 56+j16 ohms? In other words, what mechanism produced that value ? Sorry, Tom, I'm a little dense on this issue.

Walt

Roy, unfortunately for your argument, the impedance seen by the transmitter is:

Z =3D (Vfor + Vref) / (Ifor + Iref)

where the math is phasor math. ANY DEVIATION AWAY FROM THE Z0-MATCHED
LINE VALUE OF IMPEDANCE =3D Vfor/Ifor IS *CAUSED* BY THE REFLECTED WAVE!
Given that fact of physics, how can you possibly argue that the
reflected wave doesn't affect dissipation/damage at the transmitter???

Given your strange concepts that violate the laws of EM wave physics
and your ignorance of how a redistribution of energy is often
associated with the presence of interference, I feel sorry for your
students.

The power density equation containing an interference term is what you need to use and I seriously doubt that, after 5+ years, you are ignorant of that equation. In your food-for-thought, forward/reflected power example, all you have to do is figure out the power in the forward wave and the power in the reflected wave at the source resistor and plug them into the following equation:

Ptot =3D P1 + P2 + 2*SQRT(P1*P2)*cos(A)

where 'A' is the angle between the forward voltage and reflected voltage. For instance, if the reflected voltage arrives back at the source resistor in phase with the forward voltage, cos(A) =3D cos(0) =3D 1 and there is constructive interference which increases the dissipation in the source resistor. If the reflected voltage arrives back at the source resistor 180 degrees out of phase with the forward voltage, cos(A) =3D cos(180) =3D -1 and there is destructive interference which decreases the dissipation in the source resistor. If the reflected voltage arrives back at the source resistor 90 degrees out of phase, cos(A) =3D cos(90) =3D 0, and there is no interference and all of the reflected power is dissipated in the source resistor. If you had ever read my energy article, published many years ago, you would know what effect superposition accompanied by interference can have on the redistribution of energy. But you instead said, "Gobbleygook" (sic) and plonked me. Time to pull your head out of the sand.

The above power density equation not only agrees with all of your power calculations, it tells anyone who desires to acquire the knowledge, exactly where the reflected energy goes and why it is not always dissipated in the source resistor.

You seem to always note the lack of response while normal people are
trying to sleep. If Roy would simply use the power density equation
published by Dr. Best in his QEX article, he wouldn't still be
ignorant of where the reflected energy goes.

Hello boys... good day to you. You are make me study so hard forgotten stories, dusting off old books... First, I sorry for I lost some posts (I miss free news servers, ISPs here, nones!). Thanks to Roy, Owen, K1TTT, etc. I read them today.

(>: Please do not quarrel! :>). Someone said (I think it was Nikita Kruschev to the Pope, I am not sure) =3D> "If we can not agree on heaven's things, let us at least agree on the earth's things...." :>)

Why not make a "truce" for a few hours with the "why's" to verify if the proposed methods arrives at the same numerical results in terms of PRs and Pl first with our minimalistic Vg and Rs? (for the sake of novice readers)

For not to work too much, calculations could be reduced to three resistive Zls, and three lengths of TL. Let me suggest 25, 50 and 100 ohms RLs and 0.5, 0.25 and 0.125 of lambda (to honor Cecil and Roy papers), Vg voltage =3D 100 V RMS, Rs 50 ohms, Zo obviously 50 ohms too (lossless line). Zl=3D50 ohms and 1/2 lambda TL are for beginners, as me ;>D

Miguel, I gave an expression for power in your simple source circuit in a recent post, did you see it. Well here it is again:

Prs=(Vs/2-Vr)^2/Rs where Vs is the o/c source voltage, Vr is the complex reflected wave voltage equivalent, Rs is the source resistance.

If the reflected wave was always, and entirely dissipated in Rs in that type of source, then Prs=Vr^2/Zo=Vr^2/Rs... but it isn't, see the above expression.

You can work one case, three cases, three x three cases, but they are not as complete as the expression above that shows that in the steady state, Prs is not simply equal to the 'reflected power'.

But if you want, work the cases and report the results here, it is a trivial exercise. You will accept the results more readily if you work it our yourself.

Owen

Do not argue with me Owen... If you do not want put your numbers you
are free, Roy played theirs, Cecil too, it is a simple and loving
exercise of numeric agreement. No arguments, no algebra, no calculus,
no photons, no Quantum, no Maxwell, no clever and slippery words...
simple and crude numbers... Not more than five minutes. :>)

73. Here 04:26 I am go to dream with the little angels... Thanks,
Miguel LU6ETJ

> Prs is not simply equal to the 'reflected power'.

I don't remember anyone saying that Prs is equal to the reflected power and of course it is not. What you guys are missing are the effects accompanying interference from superposition. There is another mechanism besides the reflection mechanism that can redistribute the reflected power. The power density equation includes an interference term that indicates what happens to the energy.

Prs =3D Pfor + Pref + 2*SQRT(Pfor*Pref)*cos(A)

This equation gives the same answer as your equation but it also indicates what happens to the energy components. A is the phase angle between Vfor and Vref. The last term is the *interference* term.

If the interference term is zero, there is no interference and all of the reflected power is dissipated in Rs.

If the interference term is negative, there exists destructive interference at Rs and power is redistributed toward the load as constructive interference. This is technically not a reflection although the results are the same as a reflection.

If the interference term is positive, there exists constructive interference at Rs and excess power is dissipated in Rs.

Let's look at your equation, Prs=3D(Vs/2-Vr)^2/Rs

Vfor =3D Vs/2, so Prs =3D (Vfor+Vref)^2/Rs (phasor addition)

Prs =3D Vfor^2/Rs + Vref^2/Rs + 2*Vfor*Vref*cos(A)/Rs

Prs =3D Pfor + Pref + 2*SQRT(Pfor*Pref)*cos(A)

I just derived the power density equation (with its interference term) from your equation. The power density equation reveals the interference term which tells us exactly where the reflected power goes.

I learned about destructive and constructive interference at Texas A&M in the 1950s.

> For not to work too much, calculations could be reduced to three resistive Zls, and three lengths of TL. Let me suggest 25, 50 and 100 ohms RLs and 0.5, 0.25 and 0.125 of lambda (to honor Cecil and Roy papers), Vg voltage =3D 100 V RMS, Rs 50 ohms, Zo obviously 50 ohms too (lossless line). Zl=3D50 ohms and 1/2 lambda TL are for beginners, as me ;>D

Miguel, Owen's equation, Prs=3D(Vs/2-Vr)^2/Rs, and the following power density equation are equivalent and yield the same answers for Prs. However, the power density equation indicates the magnitude of interference present at Rs and the sign of the interference indicates whether the interference is destructive or constructive. This general equation is how optical physicists track the power density in their light and laser beams.

Ptot =3D P1 + P2 + 2*SQRT(P1*P2)*cos(A)

where A is the phase angle between the electric fields of wave1 and wave2. In our case, it will be the phase angle between the forward wave and the reflected wave at the source resistor.

For our purposes, based on your specifications, we can rewrite the equation:

Prs =3D Pfor + Pref + 2*SQRT(Pfor*Pref)*cos(A)

Pfor is fixed at 50 watts. For a 50 ohm load, Pref=3D0.
For a 25 ohm or 100 ohm load, Pref=3D5.556 watts.
Angle A is either 0, 90, or 180 degrees depending upon which example is being examined.

For all three of the RL=3D50 ohm examples, Pref=3D0, the line is matched and Prs =3D Prl =3D 50 watts. There is no question of where the reflected power goes because Pref=3D0.

For all three of the 0.125WL examples, since A=3D90 deg, the interference term in the power density equation is zero so for the 25 ohm and 100 ohm loads:

Prs =3D Pfor + Pref =3D 55.556 watts

When there is no interference, all the reflected power is obviously dissipated in the source resistor. This matches my "zero interference" article.

For all four of the other examples, the SWR is 2:1.
Pfor =3D 50w, Pref =3D 5.556w, Pload =3D 44.444w

If the reflected wave arrives with the electric field in phase with the forward wave,
angle A =3D 0 degrees so cos(A) =3D +1.0
The positive sign tells us that the interference is constructive.

Prs =3D Pfor + Pref + 2*SQRT(Pfor*Pref)*cos(A)

Prs =3D 50 + 5.556 + 2*SQRT(50*5.556)

Prs =3D 55.556 + 33.333 =3D 88.89 watts

In addition to the sum of the forward power and reflected power being dissipated in Rs, the source is forced to supply the additional power contained in the 33.333 watt constructive interference term.

So Psource =3D 100w + 33.333w =3D 133.33w

Because of the constructive interference, the source not only must supply the 100 watts that it supplies during matched line conditions, but it must also supply the constructive interference power of 33.333 watts.

When the reflected wave arrives at Rs 180 degrees out of phase with the forward wave,
cos(A) =3D cos(180) =3D -1.0. The negative sign indicates that the interference is destructive.

Prs =3D 50 + 5.556 - 2*SQRT(50*5.556)

Prs =3D 55.556 - 33.333 =3D 22.223 watts

The source is forced to throttle back on its power output by an amount equal to the destructive interference power of 33.33 watts. It is supplying the 22.223w dissipated in Rs plus the difference in the forward power and the reflected power.

Psource =3D Prs + Pfor - Pref =3D 66.667w

Note that the source is no longer supplying the reflected power. The

destructive interference has apparently redistributed the incident
reflected energy back toward the load as part of the forward wave.

In attempted chart form, here are the Prs values:

line length, 0.5WL, 0.25WL, 0.125WL

25 ohm load, 88.889w, 22.223w, 55.556w

50 ohm load, 50w, 50w, 50w

100 ohm load, 22.223w, 88.889w, 55.556w

Thinking about this some more, it should say:

Clearly, dissipation in Rs is related to Vr, but the contribution due to Vr is not simply Vr^2/Rs as believed by many who lack the basics of linear circuit theory to come to a correct understanding.

Thinking about this some more, the last paragraph should say:

If the reflected wave was always, and entirely dissipated in Rs in that
type of source, then Prs=a+Vr^2/Zo=a+Vr^2/Rs (where a is some constant
value)... but it isn't, see the above expression.

I see all kinds of crazy matching sections in posts about 6 meter beams. How about direct connect. I have an A4S that has major issues in the traps and I cant find the problem (IE I opened them and cant find anything) SOOO I have a new A4S coming.

Has anyone taken an old 3 elem tribander and converted it to 6 meter monobander using the direct connect.

Any Issues.

Would a 4 elem be better since its a long boom ?

I'm pretty sure I know the answers. Just want to confirm and see if there is any reason not to direct connect rather than through a hairpin or a gamma match.

To deal properly with the fact that Vr has magnitude and phase, the above
should we written as:

Prs=|(Vs/2-Vr)|^2/Rs where Vs is the o/c source voltage, Vr is the
complex reflected wave voltage equivalent, Rs is the source resistance.

If the reflected wave was always, and entirely dissipated in Rs in that
type of source, then Prs=a+|Vr|^2/Zo=a+|Vr|^2/Rs (where a is some
constant value)... but it isn't, see the above expression.

Come on, Owen, that's just a straw man. Exactly who said that Vref^2/
Rs is dissipated in Rs?

Again, a straw man. To the best of my knowledge, nobody has said that
reflected power is "entirely dissipated in Rs" (except for the special
case when interference doesn't exist.)

Hello,

For an antenna to be mounted in my attic, and for the typical scanner
frequencies, am I better off with a Disconne, or with a
Scantenna brand antenna ?
Why ?

Also, am I right that the Scantenna is Omni-directional ?

Thanks,
Bob

If you have a typical attic (inverted V) why not build your own. For a scanner you probably wouldn't notice any difference between it and a commercial one.

A guy I know used a bicycle wheel for the top hat and wires for the cone. He also reckons that its a reasonable match on two as well.

Ive done this in a pinch for a TV antenna, never tried it on a ham
band but if you pick the right size wheel I cant see why it wouldnt
work.

Ive done this in a pinch for a TV antenna, never tried it on a ham
band but if you pick the right size wheel I cant see why it wouldnt
work.

Sorry, I don't think so. The very first equation, Vf=Vs/2, would be true only if the load = Ro or for the time between system start and when the first reflection returns. For the specified steady state and arbitrary load, Vf would be a function of the impedance seen by the source which is in turn a function of the line length and load impedance.

I'm not saying an equation relating "reflected power" and source dissipation can't be written, but it does involve load impedance and line length and Z0. (Equations written with Vf and Vr as variables tend to conceal the inevitable dependence of these on line length and Z0 and load impedance, but the dependence is still there.) And the equation will show that there isn't any one-to-one correspondence between the two quantities. For a given source voltage and resistance, the source resistance dissipation depends only on the impedance seen by the source. This in turn depends on the length and Z0 of the line and the load impedance, and can be created by an infinite combination of loads and lines having different "reflected powers". As I illustrated in an earlier posting, a constant load with various lines having very different "reflected powers" can present the same impedance to the source and therefore result in the same source resistor dissipation. Likewise, different lines having the same "reflected powers" can result in different impedances seen by the source and therefore different dissipations. So the two aren't really related, even though you could write an equation which contains both terms.

Vf means the 'forward wave' voltage equivalent voltage at the source terminals.

I provide the mathematical development of the case that Vf=Vs/2 where
Rs=Ro=Zo at http://vk1od.net/blog/?p=1028 .

Can you fault that development?

Owen

> 73, Cecil, w5dxp.com

lets see one case off the top of my head... 100 ohms resistive at 1/4
wave, transformed back to the source results in 25 ohms, pure
resistive. 50 ohm source in series with 25 ohm transformed load gives
100v/75ohms =3D 1.333A from at the source terminals and 100v*25ohm/(25ohm

+50ohm) =3D 33.33V. power from the source has to equal power into the
load since the line is lossless so PL =3D 33.33v*1.333a =3D 44.44w.
power dissipated in the source resistor =3D1.333a*(100v-33.33v)=3D88.88w

no sines, no cosines, no square roots, no Pfor/Pref... so much simpler
using voltage or current and simple transformations.

I would really like to see you prove that assertion. If Rs =3D 50 ohms and Z0 =3D 50 ohms, why would the reflected wave change the forward power since the reflected wave sees a matched 50 ohm "load"? Hint: The forward power won't change unless there is a re-reflection at the source. You have deliberately designed your food-for-thought example to avoid re-reflections at the source. Lumped-circuit models seem to have atrophied a lot of brains.

Those are the kind of strange concepts that result from over-simplification of the math models. When one denies the ExH energy content of an EM wave (even a reflected wave) one chooses to follow oneself down a primrose path. Optical physicists can track their light wave energy down to the last photon. Why are some RF engineers so ignorant in the tracking of energy that they assert there is no energy in a reflected wave?

Hello Richard,

We can continue mentioning measurement results, do other claims, but
that may not converge. Your results show 50 Ohms output impedance,
mine show other. Such results cannot be verified easily, so this
remains food for endless discussions.

I decided to use another approach that can be verified by people
having a (spice) simulator. I did simulations for some circuits that
can be expected in the amateur world and aren't exotic. I put them
over here: http://www.tetech.nl/divers/PA_impedance.pdf . Now people
can figure out what it IS and get their own educated opinion. I used
low frequencies to avoid discussion about the validity of the
simulations (parasitic inductances, etc).

From these simulations it is clear that small changes in load or drive
level result in large change of output impedance. This knowledge
resulted in my statement: "an RF PA isn't a 50 Ohms source", what was/

is heavily disputed by you.

Of course you can design to have better output VSWR under varying load
or drive, but this is generally not done for systems that just have to
deliver the power (transmitters).

If you want to reproduce some of the results yourself, we can compare
our spice netlists. I recently added a real class C example as this
was heavily discussed in another thread.

Best regards,

Wim

No Richard,  I've not made that inference. The point I'm emphasizing
is that because the output resistance of these amps is non-
dissipative, no reflected power from a mismatched load enters the amp,
but is totally re-reflected in the forward direction. I make no
comment on whether the output resistance is 50 +j0, because when all
the available power is being delivered at given grid drive the output
resistance equals the load resistance, which doesn't have to be 50 +
j0. Proof of that is that when the load resistance is either increased
or decreased the output power decreases.

Hi Wim,

I quote a statement you made in your above post:

"From these simulations it is clear that small changes in load or

drive
level result in large change of output impedance. "

Now I agree that changing the drive level will result in a change in output impedance. However, let's say you have just adjusted the amp to deliver all the available power into a given load at a given drive level, and now you change the load, but leave the drive level and all other adjustments of the amp untouched. Are you saying this change in load changes the output impedance? If so, please explain why.

In addition, which situation has the greatest priority, data obtained from precise measurements or data obtained solely from simulations?

Walt, W2DU

I have reviewed Walt's additional material at http://www.w2du.com/r3ch19a.pdf .

Walt's load at step 1 is stated as 50+j0 without tolerance, but I accept that Walt is thorough and would have confidence that it is low in error. He reports Pf=100W and Pr=0, again accepted as indicating that the load and calibration impedance of the '43 are similar, and probably quite close to the nominal impedance, close enough for the purpose at hand.

At Step 8, he substitutes a load with measured impedance and calculated rho^2 as 0.235, VSWR(50) is approximately 3. Reported Pf=95W, Pr=25W, and on that basis rho^2=0.263. The discrepency in rho is not discussed in the paper.

A key observation between Step 1 and Step 8 is that changing from a VSWR (50)=1 load to a VSWR(50)=3 load resulted in a 5% change in observed Pf. This observation depends on the difference between two direct readings from a single instrument (the Bird 43), and the accuracy of calibration of both the Bird 43 and the 50 ohm load to their nominal 50+j0 impedance.

I have given a mathematical development at http://vk1od.net/blog/?p=1028 of why Pf should be independent of load impedance.

The observed change in Pf at 5% is rather small considering the load change, and suggests that Zs in this case is probably quite close to 50 +j0 although the experiment was limited to just one load case.

I make the "just one load case" condition because in my experience, a transmitter might exhibit insignificant change in Pf for some load variations, but for others it is signficant. The case I documented earlier is one such example.

Owen

I have made an error here, Walt reports Pf=95W, Pr=20W, and on that basis rho^2=0.211. The discrepency in rho is not discussed in the paper.

The error has no impact on the rest of my post.

My apologies.

Owen

I have heard that it is possible to make the antenna directional by changing the arrangement of the radials.

For example, radio hams make the radials lopsided so that it transmits and receives better in a particular direction e.g. 'aimed at Europe'.

If the vertical is the active part i.e. the radiator, what do the radials do?

Are the radials a form of counterpoise i.e. one half of a dipole?

> The same pattern can be measured in both modes.

K1TTT is correct--the transmit and receive modes are reciprocally related, and thus are identical in operation. The vertical radiator is non-directional, and is the receptor in the receiving mode. The radials are not receptors and are not involved the directivity on reception.

Walt, wouldn't that non-dissipative output resistance also reflect reverse power on other close frequencies, such as those coupled from a co-located transmission system within the bandwidth of the tx output network?

If so, such external signals would never enter the transmitter, and could not cause r-f intermodulation by mixing with the main signal in the (non-linear) PA plate circuit of that transmitter to produce a 3rd order product at 2F1 - F2, and other combinations.

But such r-f intermods are a fact of life, as shown in the Mendenhall paper, and in the existence of elaborate and expensive r-f filtering hardware needed to enable several stations to operate from one location while meeting a radiated r-f intermod spec of -80 dBc -- even from one antenna!

Richard, I'm not qualified to answer your question about intermods, so I won't even try. However, interference to the amp from radiation from an antenna driven by another amp will not be phase or frequency coherent with the tx receiving the interference. Perhaps that's the reason the interfering signal gets through while the waves reflected from a mismatch don't? In other words, could the coherent relationship between the forward and reflected waves result in the total re-

reflection at the non-dissipative output resistance of waves returning
from the mismatched load?

Walt

Measurements made of broadcast transmitters in the engineering test lab at Harris Broadcast Division show that power reflected from a mismatched load does indeed enter the PA plate output circuitry, and change the amount of power dissipation and cooling requirement for the transmitter.

That is the reason why virtually every modern manufacturer of broadcast transmitters specifies a maximum value of load VSWR for which their maximum rated powers are permissible.

For Harris FM transmitters that value is 1.7:1 (any phase angle). As the load VSWR exceeds that value the transmitter progressively "folds back" its output power to protect itself from component damage.

Another subjective term. How near is near? All products that Mendenhall shows in the illustration titled "RF spectrum showing distortion products" are 30dB down and those distortion products fall between modulation sidebands (unless you are speaking of doubling and trippling of the carrier frequency).

Returning to the amplifier of his own design, in his classic WREK engineering report [you seem shy of acknowledging your authority's work here] submitted to the FCC. Now, when I say "of his own design," I mean by him personally, at the bench, using tools, assembling components against his own schematic. He explicitly states:
"Distortion at 100% <= 1%." At "frequency removed from carrier" from -35dB to -73dB out to "600 Khz and beyond."
"Harmonic and spurious radiation" at least -70dB.
"Harmonic distortion" at 100% worst case 2.3%
"Plate efficiency of 70% to 80%"
"Total efficiency of 68%" [plate power in / RF power out]
operating Class C.

And of course his statement that sends minds reeling:

"It was thus necessary to determine the plate load impedance
    = (Eb - Emin) / I1
    ~= Eb/ Idc
    ~= 1000 Ohms
[Not very far from Walt's determination of 1400 Ohms from his own bench.]
"Since this was to be coupled into a Z output of 50 Ohms, a impedance transformation of 20:1 was needed. This was accomplished by using a voltage divider of two series capacitors to series tune the plate circuit."

His EIMAC reference found in other, later published papers conform to every detail in his engineering report to the FCC and in those same later papers. In fact, they offer a multitude of operational parameters for a variety of tubes at many power levels, across many bands and classes of operation.

Hello

Last night I was a little tired when I send my answers to Owen
stinging my eyes. It was too late and time to go to sleep :>)
I should tell owen he was inadvertently moving towards a logical
bifurcation's fallacy because is not absolutely true that Thevenin
theorem can not be used to calculate -for example- circuit efficience.
There are an exception to this limitation =3D> It can be used to
efficience calculations when disconnecting the load in the original
circuit the dissipated power is null.

Hi Wim,

Your conclusion:
"Under maximum power output matching given certain drive (not necessarily being the maximum drive), the output impedance equals the load resistor (the so-called "conjugated match condition")."

It was not the only conclusion, but it certainly disputes what you say above.

Given the easy access to real amplifiers available to Hams at their own bench, and further given that they do not present any more complexity than your own simulation; then I have to wonder why we have wandered into strange topologies.

I am not interested in trying to follow 23 pages of dense presentation where you could have simulated Walt's finals, validated or rejected his data, and THEN formed your own conclusions. If this is a problem of simulation (you don't have that tube handy) what about topology?

It looks more like a link coupled tank circuit from pre-WWII days. The Tank Q looks to be non-existent. When I rummage through the paper I find 4.4! This is certainly beyond the standard for PA design - and we have swapped out of the tube into a mosfet (would you care to stick to one objective?). Elsewhere (wandering back in tubes) I find a value of 10.3 (elsewhere it is 11) which inhabits the lowest margin of good design. Then an itinerant report of a cathode tank (????) whose Q is 0.44. Q appears to be of little concern.

Again, typical Ham equipment shows Q as low as 10 - maybe, and that would be for a dog; but those that I have seen typically fall around 15, sometimes 20. As the Z transformation in plate/drain circuits varies by the square of Q, this is not inconsequential and it once again has me wondering why the strange topology?

No, your paper lacks focus by trying to be all things (tubes, mosfets, Class AB, Class C). You examine the most inconsequential details as if they were equally important as those details that bear on your concern. The paper lacks structure. Headings are nothing more than feature descriptions, not argument development. There is a lot of discussion of the idiosyncrasies of simulation - I am not interested and that discussion creates the impression of hidden errors. Really, this stuff goes into an appendix not as the object of the narrative. The graphs are pretty diversions, but they don't add much. In the software industry, this is spaghetti design.

I would prefer a conventional topology. I suppose that has come through clear. Pick one significant point, re-edit this into 4 pages and then you might have something interesting. This advice comes from one of our American writers, Mark Twain:

> "If I had more time, I would have written you a shorter letter."

Miguel, when I said "cannot" I was of course meaning in the general case,
as most readers would understand.

Obviously there are cases where the efficiency calculations will be
correct, the obvious one being where the Thevnin equivalent is identical
to the original network.

If you want to make inferences about a source solely on the basis of its
Thevenin equivalent, you are on dangerous ground because you will not
always be correct.

People making the inference for example, that Zeq of a certain source
cannot be 50+j0 because the conversion efficiency of that source with a
50+j0 load is greater than 50% are wrong.

Owen

Convention has it that any report is understood to vary by 50% of the
least significant digit. There are other standards that do not wander
far from this simple expectation.

Hence 50�0.5+j0�0.5

Walt has an excellent GR 1606-A Bridge - same model as mine.

To give everyone some idea of what "Qualified" means in my former
trade, my bridge came with a traceable certificate of measurement that
tells me that me my accuracy:

" Resistance:
�[3.0 + 0.0024 � f� � (1 + R/1000)]% � [(X/f � 10000) + 0.1] Ohms
" Reactance:
�4.0% �(1.0 + 0.0008 R � f) Ohms
"This certificate is valid only when the bridge is balanced at the
connector reference plane and when all measurements made at this plane
are corrected as outlined in para 4.4 and 4.5 in the manufacturer's

operating manual wit the exception that the capacitive reactance to ground (Fig. 6) is computed from a value of 2.2pF. Fig. 8 should be used for the resistance dial multiplying factor."

The correction factors easily leave behind the nominal value of 1.0 for high resistance (such as Walt's 1400 Ohms) with 5% error in the 20M band, and 60% error in the 6M band. Unless, of course, you apply all corrections (the whole point of having the bridge calibrated).

>He reports Pf=100W and Pr=0, again accepted as indicating that the load
>and calibration impedance of the '43 are similar, and probably quite
>close to the nominal impedance, close enough for the purpose at hand.

Understanding what is available at Walt's bench, Pf could be off by 5W or 5%. The 0 reading also suffers the same 5W indeterminacy if it is measured on the same scale (assuming he is using a Bird wattmeter with a 100W slug).

My bridge was not remarkably far off, roughly only 1% more error in indicating the true value for resistance following corrections.

If I were to try to measure 1400 Ohms in the 20M band, I could expect it might read 1333 Ohms by dial with an error of roughly �50 Ohms.

So, between a Bird wattmeter, and it measuring power into a load with corresponding percentages of error, the we have 5% for the Bird and 3% for determining the load.

A metrologist can report these two (and there are more) sources of error by one of two ways.
1. Absolute worst case = 8% error;
2. RSS = 3.9% error
Which one picked is a function of other factors.

It doesn't take long to accumulate error and driving out variables is found only in the skill of the practice.

>At Step 8

Is a step I have no current interest in.

This needs to be put into the perspective of my last post too, as it
will impact your rho.
     Pf = 90 to 100W,
     Pr = 15 to 25W

Richard,

You can wax on all you like, and try as hard as you like, but if the source was exactly Zs=50+j0, then the Bird 43 reading for Pf should be exactly the same.

RF measurement is as you note, fraught with problems, but here is a relatively simple case. Walt reported that he adjusted the radio on a 50 ohm load, measured Pf and Pr, then substituted another load, no other changes and reported a 5% reduction in Pf.

I will leave you to arguing wether Walt's observed 5% reduction is of any value.

Anyone who accepts that a competent measurement technician, competently using the Bird 43, can reasonably discern a 5% reduction in Pf when it should be 0% if Zs=50+j0, might question whether that observation supports the proposition that Zs=50+j0.

Owen

Owen, I don't understand where you found a 5% drop in power when you say it should have been 0%. A 5% drop from what value to what value? Where did you find that data? If you're referring to 100w Pf with the 50 + j0 load and then the 95w Pf the mismatched load, you've got to understand that the source was now delivering only 75w, and the 20w of reflected power added to the 75w =3D 95w. These are two separate measurements--the first a stand-alone value and the second the sum of two values. Is this a point you overlooked?

Walt

> Owen, I don't understand where you found a 5% drop in power when you say it should have been 0%. A 5% drop from what value to what value?

Hello Walt,

I wrote an article with the mathematical development for the fact that Pf (as indicated by a properly calibrated directional wattmeter such as the Bird 43) is independent of load impedance if and only if the Thevenin source impedance is 50+j0 ohms. The article is at http://vk1od.net/blog/?p=1028 .

This provides the basis for a simple go/nogo test for the hypothesis that a particular transmitter, under particular conditions, exibits Zs=50+j0.

> Where did you find that data? If you're referring to 100w Pf with the 50 + j0 load and then the 95w Pf the mismatched load, you've got to understand that the source was now delivering only 75w, and the 20w of reflected power added to the 75w = 95w. These are two separate measurements--the first a stand-alone value and the second the sum of two values. Is this a point you overlooked?

The source is Ch 19a where you report Pf=100, Pr=0 in Step 1; and Pf=95 and Pr=20 in Step 8. I am only interested in the relative values of Pf in Step 1 (VSWR(50)=1) and Step 8 (VSWR(50)=3).

I conceded in another post that within reasonable expectations of error, and considering the load case (VSWR(50)=3), that Zs under those conditions and subject to only one load test is probably very close to 50+j0, but probably not exactly.

In one test that I conducted with a range of loads, the drop in Pf was up to 21% with VSWR(50)=1.5, but it varied with different VSWR(50)=1.5 load angles. Whilst some values supported the proposition that Zs=50+j0, others indicated that it was significantly different. Zs did not appear to be constant, it appeared to be load dependent to some extent.

Going back to your case, if the source was 50+j0, we should expect Pf=
100, and if we trust your readings from the Bird 43 as characterising the
load to have rho^2=21%, we would expect the power delivered to the load
to be 78.9W rather than 75W, and error of 0.2dB. Not a large error, but
hard to account for entirely as instrument error.

In the measurements of an IC7000 that I made, the measured output power
on one VSWR(50)=1.5 load was 82.5W when it would have been 104.6W had the
source been 50+j0, an error of 0.8dB. I opined that this test did not
support the proposition that Zs was not 50+j0

Owen

Too many "nots", isn't there?

It should read:

I opined that this test did not support the proposition that Zs was 50+j0.

Apologies, Owen.

Hi Owen,

Questions, emphatic competency, and reasonableness all in the space of
one sentence. I can see the well where you drew the literary "wax
on."

>I will leave you to arguing wether Walt's observed 5% reduction is of any
>value.

The follow-on discussion between you and Walt obviously reveals
sufficient value.

Hello Owen, OK at your comment I understand, here my apologies =>

In earlier post I write:
"The final Thevenin circuit is an idealization built with an ideal
voltage source in series with an ideal resistor. This new idealized

circuit It is a new born entity whose properties are now fully
described for these only two idealized circuit elements. These are
the
virtues and the defects of reductionist models :>("

And in the first post I was thinking about Thevenin resulting scheme
ceases to represent fully the original circuit and place the problem
in a more elementary and different situation that a real world
transmitter, enabling a clear answer to much simpler scheme for the
behavior of standing waves in such elementary context. And I thought
it was pretty clear beacuse was clear enough in my mind... :>)
When one write in his own language, normally think is communicating
very well the idea in his mind, until notice his partner take it in
another way! Difficult is multiplied when you are trying communicate
to a mind that also thinks in a different language...!
Later I realized that having formulated in terms of a simple generator
in series with a resistor would not have generated a false
interpretation and not difficult the flow of ideas.

I sincerely believe (correct me if I am wrong) this newsgroup does not
seems make (do?) efforts enough (sufficient?) to totally (completely?)
solve the more simpler cases before skip to more advanced and
sofisticated considerations on more complex systems.
For example: do you (*) recognize Roy Lewallen late example in "Food
for tought" assuming (or conceding that) as not representing a real
rig but a simple constant voltage source in series with a resistor, at
least? to give some credit to his ideas Until now, I could not
know...
(*) I do not know how clearly denote plural in "do you"

73 Miguel - LU6ETJ.
Here 04:46 LT - I am not responsible for anything written by me :>)

The relevant illustration applying to the generation of r-f
intermodulation from external signals was linked in my original quote
from Mendenhall's paper on this subject in this thread, which link I
repeat below.

It shows that the "tunrnaround loss" for external signals 0.8 MHz
offset from the carrier is as little as 5 dB, just as I posted.

By limiting limiting your understanding to the performance of an r-f
amplifier having no external influences you are missing the point of
the Mendenhall paper I referred to.

In that article, Roy says "My commercial amateur HF transceiver is probably typical of modern rigs in that it produces a constant forward average power into varying load impedances�provided the impedance isn�t extreme enough to cause the rig to severely cut back its power output."

Assuming that "constant forward average power" means 'as would be indicated on a directional wattmeter calibrated for Z=50+j0', if that is true for all load impedances that Pf is constant (within limits), then it is evidence that Zs=50+j0 (within those limits).

He goes on to say "It turns out that a linear model of my transmitter (without a transmatch) over its non-shutdown range is very simple�it�s just a voltage source in series with a resistance." Subject to the conditions I stated in the previous paragraph, that is correct, but that whilst that model can be used to determine behaviour of the external

load, there are limits to the inferences that can be drawn about the
internals of the transmitter, including as mentioned in earlier posts,
internal dissipation and efficiency. Roy acknowledges that in the next
paragraph. Only a mischief maker would represent Roy as meaning
otherwise.

From my own experience, I don't agree that HF ham rigs typically produce
constant Pf into varying loads. Walt's transmitter measurements that we
are discussing do not show constant Pf, though the change is fairly
small. But this is a practical measurement project for yourself, don't be
put off by the attempts to discredit measurements with anything but
traceable calibration.

> (*) I do not know how clearly denote plural in "do you"

I am not the expert that others are on English language, and we speak a
version of English closer to the English here... but "you" is plural and
singular (but if followed by a verb, it is treated as plural eg "you are
correct"), and you could say to a group "do you agree", though some
people may say "do you all agree" or "do y'all agree", though those might
be seen as asking each member of the group rather than collectively.

Sal's right - it's down to the quality of the item. I've seen some poor BNCs, but many PL-259s which were REAL rubbish. I expect it's because many of them are used for CB - and price is the usual decider there.

I've standardised on 50R BNCs for everything. Usually Amphenol or Greenpar - the extra cost is insignificant, compared to rig prices these days. Why 50R - the only reason is that the sockets are more robust.

Ready made BNC cables have been a disappointment - they are usually crimped, and the crimps seem to relax with age. Cables can pull out, given a bit of a tug. I use solder/clamped connectors and always solder the braid to the clamping sleeve. Never had a failure.....

> If the vertical is the active part i.e. the radiator,
> what do the radials do?

Buried radials collect the r-f earth current produced by radiation from a vertical monopole, and which are present in the earth out to about a 1/2-wavelength radius from the base of the monopole.

The net resistance to those earth currents returning to the ground connection of the antenna system at the base of the monopole is much less than when no buried wires are used, because the wires provide an alternate path with much better conductivity than provided by the earth itself.

The resistance to earth currents in that return path is in series with the radiation and other resistances in the antenna system. For best system radiation efficiency, it needs to be kept as low as possible (or practical). In the MF band, a set of 120 equally-spaced, ~1/4-wave, buried radials surrounding the radiator produces an r-f loss of less than about 2 ohms, regardless of the actual conductivity of the soil in which they are buried.

Installing buried radials over a limited azimuth sector (say, 180 degrees) won't change the directional characteristics of the monopole -- it will only reduce the value of field it produces, as a result of higher losses in the earth area around the radiator where displacement/ conducted r-f ground currents are high.

But other things equal that radiation pattern still will be circular, just a smaller circle.

RF

I agree completely with the second sentence. But the first is in error. A directional wattmeter will indeed show 50W forward and 50W reflected on a line with constant DC voltage and 0 current. I=92ll start by providing support for your second sentence and then get back to reflected power.

Choose an arbitrary point on the line and observe the voltage. The observed voltage will be a function of time. Let us call it V(t). At the same point on the line, observe the current and call it I(t).

The energy flowing (i.e. power) at this point on the line will be P(t)=3DV(t)I(t). If the voltage is measured in volts and the current in amps, then the power will be in joules/s or watts.
We can also compute the average energy flow (power) over some interval by integrating P(t) over the interval and dividing by the length of the interval. Call this Pavg. For repetitive signals it is convenient to use one period as the interval.

Note that V(t) and I(t) are arbitrary functions. The analysis applies regardless of whether V(t) is DC, a sinusoid, a step, a pulse, etc.; any arbitrary function.

To provide some examples, consider the following simple setup:
1) 50 ohm, Thevenin equivalent circuit provides 100 V in to an open circuit.
2) The generator is connected to a length of 50 ohm ideal transmission line. We will stick with ideal lines for the moment, because, until ideal lines are understood, there is no hope of understanding more complex models.
3) The ideal line is terminated in a 50 ohm resistor.

Set the generator to DC:
  V(t)=3D50V, wherever it is measured on the line
  I(t)=3D1A, wherever it is measured on the line
  P(t)=3D50W, wherever it is measured on the line
  Pavg=3D50W
No disagreement, I hope.

Set the generator to generate a sinusoid:
  V(t)=3D50sin(wt)
  I(t)=3D1sin(wt)
  P(t)=3D25+25sin(2wt)
  Pavg=3D25W
describes the observations at any point on the line.

Measurements at different points will have a different phase relationship to each due to the delay in the line. Note carefully the power function. The power at any point on the line varies from 0 to 50W with a sinusoidal pattern at twice the frequency of the voltage sinusoid. The power is always positive; that is, energy is always flowing towards the load.

Now let us remove the terminating resistor. The line is now open circuit.

Again, set the generator to DC. After one round trip time, the observations at any point on the line will be:
V(t)=3D100V
I(t)=3D0A
P(t)=3D0W
Pavg=3D0W

The story for a sinusoid is more interesting...
The observations now depend on the location on the line where the measurements are performed.
At a current 0:
V(t)=3D100sin(Wt)
I(t)=3D0A
P(t)=3D0W
Pavg=3D0W
At a voltage 0:
V(t)=3D0V
I(t)=3D2sin(wt)
P(t)=3D0W
Pavg=3D0W
Halfway between the current 0 at the load and the preceding voltage 0 (that is, 45 degrees back from the load:
V(t)=3D70.7sin(wt)
I(t)=3D1.414cos(wt)
P(t)=3D50sin(2wt)
Pavg=3D0W
This tells us that for the first quarter cycle of the voltage (V(t)), energy is flowing towards the load, with a peak of 50W, for the next quarter cycle, energy flows towards the source (peak =9650W), and so on, for an average of 0, as expected.

For a sinusoid, when the load is other than an open or a short, energy flows forward for a greater period than it flows backwards which results in a net transfer of energy towards the load.

At the location of current or voltage minima on the line, energy flow is either 0 or flows towards the load.

All of the above was described without reference to forward or reflected voltages, currents or power. It is the basic circuit theory description of what happens between two networks. It works for DC, 60 HZ, RF, sinusoids, steps, pulses, you name it. If there is any disagreement with the above, please do not read further until it is resolved.

Now it is time to introduce forward and reflected waves to the discussion. Forward an reflected waves are simply a mathematical transformation of V(t) and I(t) to another representation which can make solving problems simpler.

The transformation begins with assuming that there is a forward wave defined by Vf(t)=3DIf(t)*Z0, a reflected wave defined by Vr(t)=3DIr(t)*Z0 and that at any point on the line V(t)=3DVf(t)+Vr(t) and I(t)=3DIf(t)-Ir(t).

Since we are considering an ideal line, Z0 simplifies to R0.

Simple algebra yields:
  Vf(t)=3D(V(t)+R0*I(t))/2
  Vr(t)=3D(V(t)-R0*I(t))/2
  If(t)=3DVf(t)/R0
  Ir(t)=3DVr(t)/R0

Now these algebraically transformed expressions have all the capabilities of the original so they work for DC, 60 HZ, RF, sinusoids, steps, pulses, you name it.

Some people look at the expression If(t)=3DVf(t)/R0 and think it looks a lot like a travelling wave so they decide to compute the energy being moved by this wave:
  Pf(t)=3DVf(t)*Vf(t)/R0
  Pr(t)=3DVr(t)*Vr(t)/R0

So let us explore the results when applied to the DC examples from above.

Terminated with 50 ohms:
  Vf(t)=3D50V
  If(t)=3D1A
  Vr(t)=3D0V
  Ir(t)=3D0A

  Pf(t)=3D50W
  Pr(t)=3D0W

This all looks good, no reflected wave and the appropriate amount of energy is being transported in the forward wave.

Let us try the open ended line:

Vf(t)=3D50V
If(t)=3D1A
Vr(t)=3D50V
Ir(t)=3D1A

which yield
V(t)=3DVf(t)+Vr(t)=3D100V
I(t)=3DIf(t)-Ir(t)=3D0A

which is in agreement with the observations. But there is definitely a forward voltage wave and a reflected voltage wave. Carrying on to compute powers:
Pf(t)=3D50W
Pr(t)=3D50W
and
P(t)=3DPf(t)-Pr(t)=3D0W

So there you have it. The interpretation that the forward and reflected wave are real and transport energy leads to the conclusion that on a line charged to a constant DC voltage, energy is flowing in the forward direction and energy is flowing in the reflected direction.

Because it is obvious that there is no energy flowing on the line, this interpretation makes me quite uncomfortable.

Now there are several ways out of this dilemma.

Some say they are only interested in RF (and optics), and that nothing can be learned from DC, steps, pulses or other functions. They simply ignore the data and continue with their beliefs.

Some claim that DC is special, but looking at the equations, there is no reason to expect the analysis to collapse with DC.

The best choice is to give up on the interpretation that the forward and reflected voltage waves necessarily transport energy. Consider them to be a figment of the analysis technique; very convenient, but not necessarily representing anything real.

As an added bonus, giving up on this interpretation will remove the need to search for =93where the reflected power goes=94 and free the mind for investment in activities that might yield meaningful results.

> Walt, W2DU

Hello Walt,

I think it does, changing the load will change the output impedance.
The root cause is that under conjugated match conditions (given fixed
input drive, constant supply voltage, etc), the active device is
operating on the edge of voltage saturation.

When you reduce the load resistor (parallel representation, and seen
from the plate), the RF plate voltage drops, causing the valve to
operate more like a current source. Increasing the load resistance
will result in voltage clipping, so plate voltage rise with increasing
load resistance is limited.

One can also say that (under voltage saturation), during a small portion of T, the plate voltage is shorted to ground via about 120 Ohms (derived from DC characteristic of 6146 valve).

I added page numbers to the document (it is at the same location). When you look at page 3 you can see the simulation results. Output impedance (based on deltaV/deltaI with different load resistors) changes from above 9 kOhms to below 1000 Ohms. For load changes of less the VSWR =3D 1.2.

When the valve is operated below voltage saturation (for example due to decrease of load resistance or drive reduction), the output impedance is less dependent on load change and the amplifier will more or less behave like a linear circuit. You can see this on page 8. That table is for a situation where the plate voltage is below the amplitude that causes voltage saturation of the tube. Look also to the power supplied to the load, there is no conjugated match.

Regarding simulation.
I am fully aware of the limitations of simulation. I did compare the data sheet curves with simulated curves first. The simulated one has a somewhat steeper transition between current saturation region and voltage saturation region. This will result in some more output impedance change versus plate RF voltage, but doesn=92t make the simulations useless. the low Q in the cathode was just for making the cathode voltage more sinusoidal to enable to guess the actual input power.

My observations resulting in my statement regarding output impedance of amplifiers were from the time that I never simulated a PA. They are from measurements and reasoning starting from the time that I was in school designing a solid-state (BLW76 bipolar transistor) amplifier with third harmonic peaking. Referencing to measurement will likely result in endless discussions, even when publishing the full details. To avoid this, I did some simulations (with the risk that people may waive this also).

In my opinion it is too easy to waive results that are from simulation as some other people are trying. Simulation is standard practice in the design flow.

I hope you concluded that the simulations do not dispute most of your findings, even the conjugated match with high efficiency is still standing (which is disputed by others). The only thing I tried to support is that many real world amplifiers under practical operating conditions do no show output impedance equal to the specified load and that therefore answering "what happens with reflected energy?" is not just a simple transmission line problem. I therefore added also a simple non-exotic mosfet stage for FM/CW operation as many people use solid-state PAs.

Best regards,

Wim

> Given the easy access to real amplifiers available to Hams at their own bench, and further given that they do not present any more complexity than your own simulation; then I have to wonder why we have wandered into strange topologies.

My findings are from practice before I had the opportunity to do PA simulations.

>
> I am not interested in trying to follow 23 pages of dense presentation where you could have simulated Walt's finals, validated or rejected his data, and THEN formed your own conclusions. =A0If this is a problem of simulation (you don't have that tube handy) what about topology? =A0

23 pages is not that much as graphs and circuit diagrams dominate. If you can provide me a circuit diagram I will figure out whether I can simulate it or not.

>
> It looks more like a link coupled tank circuit from pre-WWII days. The Tank Q looks to be non-existent. =A0When I rummage through the paper I find 4.4! =A0This is certainly beyond the standard for PA design - and we have swapped out of the tube into a mosfet (would you care to stick to one objective?). =A0Elsewhere (wandering back in tubes) I find a value of 10.3 (elsewhere it is 11) which inhabits the lowest margin of good design. =A0Then an itinerant report of a cathode tank (????) whose Q is 0.44. =A0Q appears to be of little concern.

Fully agree with the low cathode Q, therefore it doesn't affect the simulations results significantly.

>
> Again, typical Ham equipment shows Q as low as 10 - maybe, and that would be for a dog; but those that I have seen typically fall around 15, sometimes 20. =A0As the Z transformation in plate/drain circuits varies by the square of Q, this is not inconsequential and it once again has me wondering why the strange topology?

Tell me what Q I should use (evt, give me component values) in the simulation, and I will change it for you.

>
> No, your paper lacks focus by trying to be all things (tubes, mosfets,

> Class AB, Class C). =A0

This is to support my statement that under real world amateur
conditions many PAs do not obey ZL =3D Zout*. If I have some time I will
add a push-pull transfomer coupled amplifier also.

You examine the most inconsequential details as

etter."
>
> 73's
> Richard Clark, KB7QHC

simulation is general practice in the design flow, I know it has
limitations. Of course I could use ADS, but most people don't have
that at home, so I decided to use spice as this is used by many.

If you believe I am so wrong, why don't you present some simulations
to show that my original statement is completely wrong?

Best regards,

Wim

You would do well to download EZNEC and give your ideas a try. You will find that the best directivity comes with only one radial. There is about 4dB difference between the side and front(or back) of the *total* radiation pattern. However, you will see that this directivity comes at the expense of increasing the horizontal polarization and decreasing the vertical polarization. This might be okay, depending on your circumstances. That's why I suggest you use EZNEC -- only you know what is acceptable for your case.

Good luck.

John

> Was your disingenuity deliberate?

No, it was non-existent. The source I referred to was Roy's *specified
source* in his food-for-thought article on forward and reflected
power. Roy used his *specified source* to do his power calculations.
Contrary to what you asserted, Roy certainly did "make an inference
about the internal dissipation of the source". The fact that Roy's
specified source doesn't resemble a ham transmitter is irrelevant.

John, are you using EZNEC to model radials in the ground or above-
ground? If you're modeling in-ground radials then you must be using
EZNEC incorrectly t o obtain directivity other than omni-directonal,
because the directivity of any vertical radiator is equal in every
direction, regardless of the number of radials, zero or an infinite
number. In other words the radiator is omni-directional. On the other
hand, if you're modeling an above-ground radiator with only one
radial, then of course the radiation will include both vertical and
horizontal components, which result in a polarization angle other than
either vertical or horizontal and will likely have radiation that is
not omni-directional.

I've got a copy of the 3rd edition of that very book. S-parameters are
covered on page 540 so my question remains. Why don't RF engineers
read the book?

Ah, but you said you could calculate "them", meaning at least two
voltages. You have calculated one voltage to be zero. So what is the
value of one of the other voltages when the Z0 is unknown?

Hi Wim,

I'm glad you wish to examine this more.   I will send you Mendenhall's
400W FM design done 42 years ago to this month and nearly day. I will
also send a partial schematic for Walt's TS-830s.

Mendenhall's is not very different from your own model except with a
far more powerful VHF Tube, however, it is a tetrode design too.
Walt's is a pair of pentodes. See what you can do.

>Fully agree with the low cathode Q, therefore it doesn't affect the
>simulations results significantly.

Why a Common Grid design for a tetrode tube?

>Tell me what Q I should use (evt, give me component values) in the simulation, and I will change it for you.

15 is one that Terman cites, and Mendenhall cites Terman, and Walt's (if I recall correctly) also find a similar value. Given your especially low frequency simulation, component values are way out from those commonly encountered in HF/VHF work.

>> No, your paper lacks focus by trying to be all things (tubes, mosfets, Class AB, Class C). �
>
>This is to support my statement that under real world amateur conditions many PAs do not obey ZL = Zout*. If I have some time I will add a push-pull transfomer coupled amplifier also.

Then you should do the finals deck for a transistor rig for that topology. It would bring you into the 21st century (even if the details still date from the 1970s). You will also find more simulation options.

>simulation is general practice in the design flow, I know it has limitations. Of course I could use ADS, but most people don't have that at home, so I decided to use spice as this is used by many.

One of the titans of linear design, Bob Pease of National Semiconductor had little sympathy for those who discovered the problems of simulation. However, those who read his work were sure to avoid pain and trauma. Consult:
http://www.national.com/rap/

Having said that, it is somewhat ironic that we all use simulation for antennas - so we are all aware of limitation and possibility. I have used many simulators from a spectrum of disciplines.

>If you believe I am so wrong, why don't you present some simulations to show that my original statement is completely wrong?

You have more time and passion for it. I have already had a career in testing these issues specifically and proof is at the bench. I was trained to demanding methods for this and I worked with the most accurate instruments in the world. However, I don't expect equal results. If you wish to work further with the two schematics I send you, then that would interest me far more than the banalities of photonic explanations and spreadsheet solutions.

I am not saying anything you have done is wrong, I am saying that your style is getting in the way of communication. It reads like a detective novel, not a like presentation. You discover conclusions, you don't seem to test for expectations. Surprise and mystery arrive haphazardly through the narrative. Inconsequential details are mulled over like Holmes describing the characteristics of cigar ash to Watson.

You are trying to do too many things in one place and the topic begins to blurs and the goal is distracted. For instance, this thread's subject line of "what happens to reflected energy?" is never summarized in your final conclusion - that is not good reportage. I went to that last section and saw that discussion missing. Closer examination revealed it by parts as seemingly trivial observations.

For style, start with a good grounding. Establish a base line. Do a Monte Carlo analysis of a known design with known characteristics. Then introduce a hypothesis tied to one variable. Push the variable and note how it either conforms or strays from your hypothesis. Present your work. Have a discussion to shake out problems of understanding (from anyone). Then move on to either shift the topology, or further stress the existing design. Build on a solid foundation.

Schematics will follow as soon as I can make their file sizes suitable for email servers (about 1-2 MB).

I should have used arrows rather than equals signs.
But it's basically a manifestation of Chu's idea combined with practical
materials.

Chu proposed the concept relating directivity and stored energy and
physical size. A passively excited multi element array (like a Yagi) has
to transfer energy from element to element to work, and it follows the
characteristics outlined by Chu. And anything with circulating energy
that gets carried by a conductor is going to have high(er) I2R losses
than something that doesn't.

it may be true for a specific type of
> antenna, MAYBE Yagi's, MAYBE rhombics or or close coupled wire arrays,
> but some of the most directive antennas are parabolic dishes which i
> would expect to have very low Q and extremely low losses.

Interesting case there. Loss isn't all that low (typical parabolic
antennas with their feed have an efficiency of 50-70%), although it IS
low compared to the directivity. And, in fact, there's not much stored
energy (so the Q is low). On the other hand a parabolic antenna is
physically very large compared to a wavelength, so the Chu relationship
holds. I'd have to think about whether one can count the energy in the
wave propagating from feed to reflector surface as "stored", but I think
not. Probably only the E and H fields at the reflector surface.

you could
> also have an antenna with very high Q, very high i^2r losses, but very
> low directivity, so i would be careful about drawing a direct link
> between the two.

Yes.. you're right.. the relations set an upper bound on what's
possible.. That is, for a given directivity, you can get either small
size and large stored energy (the Yagi-Uda or W8JK), or large size and
small stored energy (the parabolic reflector and feed). As you note, a
dummy load has very low directivity.

I suppose this will be buried where nobody will read it...

I realized that with the nice instrument-grade directional couplers that came with a new 100W RF power amplifier, and with the other equipment on my bench, I can measure RF amplifier/transmitter source impedance relatively easily and with good accuracy. I strongly suspect the accuracy will be limited first by how well the setup of the transmitter/amplifier can be duplicated, and not by the measurement instruments.

I won't go through the whole test setup, but just say that substituting an open or short for the connection to the transmitter yields the expected amplitude return signal, and terminating the line in a precision 50 ohm calibration standard yields a 47dB return loss, for the frequency I was measuring (nominally 7MHz, for this first measurement). The measurement involves sending a signal offset from the nominal transmitter frequency by a few Hertz at about -20dBm toward the transmitter, and looking at what comes back.

Measuring a Kenwood TS520S, set up for about 70 watts output, ALC disabled, operating as a linear amplifier somewhat (about 30 watts) below its maximum output: result is 56+j16 ohms at the output UHF connector on the TS520S. That's about 1.4:1 SWR, and at some point along a lossless line, that's equivalent to about 70+j0 ohms: not terribly close to 50 ohms. I'm not going to bother with a detailed error analysis presentation, but I'm confident that the amplitude of the return loss is accurate within 0.1dB, and the phase angle within 10 degrees, to better than 99% probability.

I may make some more measurements with different amplifier setups and at different frequencies, but for now, that's it...

Cheers,
Tom

This is repetitive without being informative. I am satisfied with Mendenhall's clear statements about plate resistance in how to fine tune finals - a paper that is obviously on-topic. I am satisfied with his WREK design (as was the FCC). I see he observed standard methods of design and cites accessible authorities that guide industry. I don't need to elaborate what he offers by mincing around the issue with interpretation, inference, and suggestion.

To offer what you think is contrary evidence goes well toward impeaching your own authority. There is no amount of discussion or even agreement that can balance that contradiction. From the content of your other discussion, you are arguing both sides, or you are turning this on the pivot of an opaque detail known only to you.

I am satisfied that the general readership has all the details. Or
could ask for them if this was interesting.

So am I.

What they mean to each reader depends on his/her ability and
willingness to comprehend what was given in the Mendenhall paper I

quoted, and not to refer to data taken on an r-f amplifier operating
under conditions having no specific relevance to the Mendenhall paper
about turnaround loss.

Except the high Z value for the Common Cathode amplifier, all results
are as expected. Otherwise I did not make my statement on the output
impedance of PAs.

You disputed my statement on Zout and came up with the "what IS it"
attitude, I only provided information so that other people can get
their own opinion. I prefer to keep the focus on that.

Before I am going to spend lots into time this, some points:

1. Do you accept the "measuring" method with injecting a signal with slight frequency difference as mentioned in the document?

2. Do you accept the way of presentation (envelope change versus time and converted to output VSWR as used in the document)?

3. Do you accept B^2 spice A/D professional, version for as suitable platform?

If we cannot agree on this, it is of no use to continue.

I limit the simulation to low HF frequencies as based on a circuit diagram alone we cannot guess the parasitics for high HF/VHF use and this may be food for more discussion. Please also mention what components you want into the simulation as simulating a full TS830 will take to long.

All relevant info will be made available to the group, inclusive original circuit diagrams and the diagrams I used for simulation. I hope that I can get a suitable simulation model for the tubes.

Regarding circuit diagrams, can you reduce the color depth (gray scale or B/W) and convert them to PNG as this is non-lossy coding.

I am looking forward to the results.

Best regards,

Wim

Making some assumptions about a sensible implementation for the test, an interesting test Tom, thanks for the writeup.

One of the interesting propostions emerging in the discussion is that Zs may be dependent on drive level. Your test setup would be an interesting one to explore that effect (changing drive level alone, no other adjustment or change).

In my own tests looking for Pf constant (independent of load changes), I have noted that I get different results from the IC7000 at different drive levels. Not surprising, as the gain of the active devices are likely to change significantly in the upper half of the rated power range, and the effects of either current or voltage saturation are likely to be manifest at near rated output, and power control loops at maximum output.

If Zs is dependent on drive level in a significant way, then one must ask what is the application of Zs in the case of an SSB telephony transmitter.

Owen

if you can choose an arbitrary point, i can choose an arbitrary
time... call it a VERY long time after the load is disconnected.

only if this is a case WITH a load... this is not what we were discussing above.

ok, p(t)=3D0w, i=3D0a, i connect my directional wattmeter at some very long time after the load is disconnected so the transients can be ignored and i measure 0w forever. there is no power flowing in the line.

so you have derived voltages and currents at a couple of special locations where superposition causes maximum or minimum voltages or currents... this of course ONLY works after sinusoidal steady state has been achieved, so your cases of connecting and disconnecting the load must be thrown out. and how do you find a maximum or minimum when the load is matched to the line impedance? standing waves are always a trap... step back from the light and come back to the truth and learn how to properly account for forward and reflected waves with voltages or currents and all will be revealed.

hmmm, they work for all waveforms you say... even dc?? ok, open circuit load, z0=3D50, dc source of 100v with 50ohm thevenin resistance...

If(t) =3D 100/50 =3D 2a
Ir(t) =3D 100/50 =3D 2a

so there is a reflected 2a current you say? where does that go when it gets back to the source? we know that when the 100v source is open circuited as it must be in this case that it develops 100v across its terminals... sure doesn't seem like any way that 2a can go back into the source. it can't be reflected since the source impedance matches the line impedance. so where does it go? maybe those simple algebraic expressions have to be reconsidered a bit.

well, maybe i missed something... lets look at the voltages:

Vf(t)=3D(100+50*2)/2 =3D 100
Vr(t)=3D(100-50*2)/2 =3D 0

hmm, you do seem to get the right constant voltage... but it kind of messes up your power flow since Vr=3D0 there can be no power in that reflected wave, so it really doesn't make it much of a wave.

but wait, the equations must be consistent so

Ir(t)=3D0/50

So there really is no reflected current... but there is forward current? so where does that forward current go if there is no load? it doesn't reflect back if Ir=3D0... does it just build up at the open end? going to be lots of trons sitting there after a while.

sorry, you can't have a 'voltage wave' without a 'current wave'...
just doesn't work i'm afraid. to have one you must have the other.

Comparing to my table of results for my own TS430S, with similar
initical conditions, that is well within the range of measurements I
have taken.

Hi Wim,

I got only a hint of what you were trying to do because it was buried in so much conflicting agendas.

However, my first impression was that it looked worth discussing. My second impression was that it was not needed. Still, that is worth discussing too.

>2. Do you accept the way of presentation (envelope change versus time
>and converted to output VSWR as used in the document)?

I hadn't the slightest idea what that was all about. Like I said, too many things going on. From your email, it sounds like too much complexity to accomplish what was done with meter indications.

For others, this might be found in the section called "Output Tuning" in:
"Fine Tuning FM Final Stages," by Mendenhall (google for a link or email me for a copy).

>3. Do you accept B^2 spice A/D professional, version for as suitable
>platform?

I have no problem with what you are comfortable with. I am sure a suitable simulation will evolve.

We will resolve the details offline. I would encourage you to save effort (we both have things to do) by doing a "quick and dirty" first pass just to see how little we may have left to do (it could be that simple). There is more to read than there is to simulate.

For others, the material I have linked Wim to probably tips the
download scale at 50MB. 44 MB is one document alone that others here
might find useful:
"EIMAC Care and Feeding of Power Grid Tubes" 44MB at:
http://www.g8wrb.org/data/Eimac/care_and_feeding_of_power_grid_tubes.pdf

It will brush away the cobwebs.

Tom, you stated earlier that you measured the source impedance of a TS520S transceiver by inserting a somewhat off-resonance signal into the output terminals when the rig was delivering 70 watts, and the source impedance was measured as 56+j16 ohms. However, you chose not to describe the setup or the procedure for obtaining this data.

I'm hungering to learn of the setup and procedure you used, because I'd like to know what reflection mechanism gave a return signal that could be discriminated from the 70w output signal from the transceiver.

In his Nov 1991 QST article Warren Bruene, W5OLY, used what I believe is a similar procedure, in which he claims he measured the Rs that he called the 'source impedance' of the RF amp. He used his measurements in asserting that because his Rs didn't equal RL there could be no conjugate match when the source is an RF power amp. I have never believed his procedure and measurements were valid, and I still don't. So if your setup in any way resembles what Bruene presented in his QST article I would like to know how you can justify a procedure that involves inserting an off-set frequency signal rearward into an operating RF power amp to determine the source impedance.

Walt, W2DU

Hi, Walt -

Above ground about 2 wavelengths and, yes, the vertical component is
omnidirectional. It is the horizontal component that gives some
directivity as you said. I think I used the wrong phrase above. I said,
"increasing the horizontal polarization" when I probably should have
said "increasing the horizontally-polarized field". Ditto for the
vertically-polarized field.

If I still have it phrased wrong, please help. This is the sort of thing
that happens when you turn an old fart loose with a simulator.

John, KD5YI

OK...

So let's consider making a load-pull measurement of source impedance. Since we're trying to resolve both resistance and reactance, we need to change the load in at least two directions that have a degree of orthogonality. But we could also change the load over a range of values. For example, we could connect a 51+j0 load directly to the output port we're trying to measure, and then connect it through varying lengths of 50.0 ohm lossless coax. 45 electrical degrees of line would shift the phase of the 51 ohm load so it looks instead like 49.99-j0.99 ohms. 90 electrical degrees shifts the 51 ohm load to 49.02+j0 ohms, and so forth. Measurements of the varying amplitude output with those loads will give us enough information to resolve the source resistance and reactance and open-circuit voltage.

For a 51 ohm load on a 50 ohm line, the reflection coefficient magnitude is 1/100, so if the transmitter is putting out 100Vrms forward, the reverse is 1Vrms.

Now consider a method to change the line length that doesn't use individual sections that have to be patched in and out, but rather uses a "trombone" section that, in theory anyway, could range from zero length to essentially infinite length. Picture that trombone section getting longer at a fixed rate, so now the load is rotating around a circle on the linear reflection coefficient plane (which is, by the way, exactly the same plane the Smith chart is plotted on); the circle is centered at zero and is a constant 1/100 amplitude, with linearly varying phase. So the 1Vrms reverse wave on the line of the 100Vrms forward example arrives back at the amplifier at continuously varying phase. Imagine that the phase shift is 360 degrees in 1/100 of a second. Now note that the reverse wave corresponds _exactly_ to a wave offset in frequency from the forward wave by 100Hz. If the line is continuously lengthening, the offset is negative; if the line is shortening instead, the offset is positive.

Now, from the point of view of the amplifier, can that scenario be distinguished from one in which I have a perfect 50 ohm load that absorbs all the transmitter's output, and a method to introduce a "reverse" 1.00Vrms wave into the line at a frequency that's offset from the transmitter's output by 100Hz?

If you believe that the amplifier can distinguish between those two scenarios, I fear we have nothing more to discuss.

Cheers,
Tom

Thanks Owen. I believe I quite understand your kind explanation and
reasons, but I am not sure if I can ask my question well enough

indeed!. I beg your patient.
I am not interested yet to make questions about real rigs, but reduce
at first only one specific problem at the most simple theorical model
I can think: an ideal constant voltage source in series with an ideal
resistence loaded at first with simple resistive loads connected
directly and late via ideal lossless TL of differents simple
wavelenghts 1/2, 1/4, 1/8 (I have formed idea about this, but I am not
interested in my concept but your concept about it).
For example, I want to know if you (all) would predict identical Rs
and Rl dissipation in that reduced and theorical context with direct
and remotely connected loads (vinculated via TL).

To this point K1TTT -seem to me- tell me you all would agree to settle
the problem with Telegrapher's equations to obtain TL input Z and then
apply simple circuit theory solution to calculate Rs-Rl dissipation
(before begin Thevenin misleading issue).
I do not want to advance more from here for fear to complicate the
question with my translation.

Thanks again.
Miguel - LU6ETJ

ok, so you defined a case where the superposition of the reflected and
refracted waves at a discontinuity results in a zero sum.  is that
supposed to prove something?  did i ever say that you could not define
such a case??

Hi Owen,

Well I see neither data of that Z over Loads over Power over
Frequency, nor do I read what you would call what is "usable."

>The meaning of "sufficiently" is proposed in the reference article
>describing the test and providing the mathematical basis for the test.

"Sufficiently" is a subjective term for which I see no objective
criteria.

>My recollection of Walt's tests were that they tested at points other
>than Zl=0 and Zl=infinity.

Steps 1 and 2 are quite explicit.

>You dwell at some further length on the implicit accuracy of the stated
>quantity, but ignore the explicit discussion about a reasonable tolerance
>for the test.

I see no further discussion of my observation of the possibility of 51 Ohms being, in your terms, "usable, sufficient, or reasonable," so I dwell on what is known, and not on vacant adjectives.

It is my understanding that the average power (heat) generated at the anode of a triode can be found by averaging the product of the instantaneous anode current and anode-cathode voltage over time. In a Class C amplifier, the voltage and current are not linearly related to each other, ie there is no constant of proportionality, no constant or fixed resistance.

I don't understand why then, that people try to explain the anode dissipation in terms of some value of resistance.

Richard,

The article does propose a practical tolerance. I quote the relevant paragraph below.

"Of course, nothing is perfect so an acceptable tolerance for depending on the assumed Zs=50+j0? for Mismatch Loss calculations might be that �forward power� doesn�t vary by more than 10% of the �reflected power� at any point.

The worst case �reflected power� for the experiment as described is 4%, so a variation of �forward power� by more than 0.4% (ie 0.4W in 100W) at any point would indicate significant error in any Mismatch calculations based on an assumed Zs=50+j0?."

I explained in the articles how I am able to reliably detect such small relative power variation. In one of the tests, the measured variation was 21%.

My intention in publishing the two articles wasn't to prove the propostion one way or the other, but to show practical amateurs a test that they could make with relatively simple equipment, one that is relevant to the application of Zs if it was known, and an explanation of why it works so that they can understand the test and make their own interpretations about significance.

Owen

Hello Owen thank you for your answer: Sorry I do not quite understand
your answer. I choose a Thevenin model of circuit theory because it is
an idealization consisting of an idealized constant voltaje source in
series with an idealized resistance without any relation with
practical implementation of such imaginary electrical (and
mathematical) entity.

I first interested get from you such idealized model answer as a
reductionistic aproximation method to try arrive later at subsequent
interpretations of practical situations. I think we all used to
working with idealized models and we accept its limitations, but we
also know frequently they are very useful to clear the "field" (as in
football "field")
(I said "never" because Cecil seem say "sometimes").
For example: ideal conjugate mirror in Maxwell article in my
interpretation implicates "never". Reflected power do not return to
the source in that context.
If you prefer I would be equally satisfied knowing who agree with
"never", who with "sometimes" and who with "always". But I would not
be too annoying :>)

I would call two waves superposing to zero indefinitely, "wave cancellation". If that is not wave cancellation, where did the reflected and refracted wavefronts go along with their energy components? The answer to that question will reveal exactly what happens to the reflected energy.

Here's a brain teaser for you and others. Given a Z01 to Z02 impedance discontinuity with a power reflection coefficient of 0.25 at the '+' discontinuity:

```
------Z01-----+------Z02-------load
```

Pfor1 in the Z01 section is 100 watts. Pref1 in the Z01 section is zero watts.

What is Pfor2, Pref2, and the SWR in the Z02 section?

Hi David,

In the proximity of an antenna, you do not encounter mirror-like reflections, nor anything approaching them. I am sure you have seen tutorials or references that give the appearance of reflection in association with an antenna. However, if you look closely, those reflections are in the far-field (some several to tens to hundreds... of wavelengths away).

This reflection metaphor is generally illustrated with explanations of ground mounted verticals. It is a useful concept that is only observed at a great distance. In other words, for it to work the way they show it, you can't get close enough to observe it.

Hi Richard,

Deja Vu all over again. I suppose you posted this to inspire me to, once again, remind you from Mendenhall's own notes about Class C amplifier construction - and so I will:

"It was thus necessary to determine the plate load impedance
= (Eb - Emin) / I1
~= Eb/ Idc
~= 1000 Ohms
[Not very far from Walt's determination of 1400 Ohms from his own bench.]
"Since this was to be coupled into a Z output of 50 Ohms, a impedance transformation of 20:1 was needed. This was accomplished by using a voltage divider of two series capacitors to series tune the plate circuit."

The tube is an EIMAC 4CX300A running no where near capacity.

All details (and more) written in Mendenhall's own hand.

Miguel,

From Wikipedia: "Th�venin's theorem for linear electrical networks states that any combination of voltage sources, current sources and resistors with two terminals is electrically equivalent to a single voltage source V and a single series resistor R. For single frequency AC systems the theorem can also be applied to general impedances, not just resistors."

The theorem does not state or imply that the Thevenin equivalent circuit dissipates the same internal power as the real source, just that any *linear* two terminal circuit containing sources and impedances can be reduced to this two component equivalent (at a single frequency), and V and I at the network terminals will be the same as the original network, irrespective of the external load attached to the network terminals.

It is a simple exercise to develop two source networks with the same Thevenin equivalent circuit, but that have quite different internal efficiencies. It is easy to demonstrate that both networks deliver the same power to any given load, but that the internal dissipation of those source networks is different in both cases, and not explainable simply as absorbing 'reflected power'.

This is basic linear circuit theory.

If there was a valid Thevenin equivalent circuit for a transmitter (and that is questionable), then you can not use that equivalent circuit to make any inference about the internal dissipation of the source (the transmitter in this case), or its efficiency. Nevertheless, I see people trying to do this one way or another in the various threads here.

> (I said "never" because Cecil seem say "sometimes").
> For example: ideal conjugate mirror in Maxwell article in my

> the source in that context.
> If you prefer I would be equally satisfied knowing who agree with
> "never", who with "sometimes" and who with "always". But I would not
> be too annoying :>)

I know that in this age of instant gratification, people reading posts in these fora tend to accept simple dogmatic statements as sure sign of author credibility, and qualifications such as 'often', 'usually' etc as a sign of uncertainty, of a lack of understanding, of weakness in the author. The opposite is often, if not usually true.

In English, we have a saying "never say never".

What 'never'? 'Hardly ever'... to borrow some dialogue.

A man who is hardly ever wrong doesn't use words like 'always' and 'never' much, or imply as much in general statements.

Owen

A lossless line infinite in extent is the typical definition that corresponds to its characteristic "non-dissipative" resistance. That, or it is terminated in a lossy resistor (and the loss is suddenly in everone's face, full and foursquare).

How long are you going to wait to finish the energy budget to measure IF there is missing energy from an infinite line?

But what lead us here was that you had proof, at least through some third party (the experience of your having seen something that diminished the "proposition"). I asked for that specifically. I have not seen any reputable counter to Walt's data supporting the "proposition."

The point remains that out of tolerance loads do not invalidate the "proposition:"
>On Fri, 11 Jun 2010 20:31:42 GMT, Owen Duffy <none@no.where> wrote:
>
>>there is a proposition that a transmitter "designed/adjusted
>>for, and expecting a 50 + j 0 ohm load" can be well represented by a
>>Thevenin equivalent circuit and naturally has Zeq=50+j0.
In fact they announce themselves as violating the "proposition."

I hope this does not return us to the vacant adjectives, which as an English major, I can full well argue to greater advantage. I don't think that is productive, but choices remain to pursue them, or to introduce new facts.

****

Now, let's return to your paragraph, how do you know where the 50 Ohm point was? You are relying on relative accuracy to make an absolute measurement. This only works if you have a standard to make a transfer from. Walt did this but it is arguable that his 1400 Ohm resistor was, in fact, that value - however, he had the correct tools to measure it.

Your two test results could be inverted (fail/pass for pass/fail), or they could both be pass, or both fail.

I have calibrated many loads from DC to 12 GHz - and most of them failed for many and sundry reasons and had to be "qualified." In the vernacular of the standards laboratories that means a table of correction values that are valid as long as certain characteristics are met. I prepared many such lengthy reports as no one was going to buy a new load each calibration cycle (typically 3 or 6 months).

I own one that met 1% accuracy out to 1GHz (@150W), but that was luck of the draw and I wouldn't be so naive as to claim it retains that accuracy - however, experience has revealed that with care it should. Aging loads is like aging wine - there is no stasis. Here we get back into subjectives, but I know the limits of care, and I know how to practice it. If pressed to prove my inference of 1%, I also have the skill to do so to that accuracy according to methods practiced by Metrologists. It would be exceedingly tedious. Exceedingly tedious. Or I could pay for it to be done.

From Mendenhall:

"VHF amplifiers often exhibit a somewhat unusual characteristic when tuning for maximum efficiency. ... If the amplifier is tuned exactly to resonance, the plate load impedance will be purely resistive and teh load line will be linear."

From "Care and Feeding of Power Grid Tubes:"

"The first step in designing the output circuit is to specify the resonant load impedance of the tube, the loaded Q of the circuit and the desired output impedance of the network. The resonant plate load impedance for the 4065A is determined by dividing the plate peak RF

voltage swing by the plate peak fundamental RF current.
[work shows Resonant load impedance = 7600 Ohms]
"if it is assumed that the output impedance of the network is to be 50 Ohms, and the loaded Q is to be 15, the output tuned circuit may now be designed. The output impedance of 50 Ohms will match into a properly terminated 50 Ohm transmission line."

This document provides plenty of math and charts for the design of efficient output networks (finals' plate load).

Hello Owen, good day in Australia I hope!

Sorry, with due respect, your answer throws back the ball out of the
soccer field :>)
I like poetry also but would you mind search the web for another
scientific uses of "never" word?, such as in
http://www.upscale.utoronto.ca/PVB/Harrison/Entropy/Entropy.html.

Of course many thanks for your time and your kind reply.

Miguel LU6ETJ

Hi Miguel,

Lastly first, your reference uses "never" in the statement of a law of physics. That might be a safer place to use it than your typical ham assertions like "a non-resonant antenna is never going to work as good as a resonant one".

I am not sure what "throws the ball out of field". Is it the misuse of Thevenin equivalent circuits?

I tempted you to an exercise. In case you didn't try it, try this one.

I have three ideal components, a 1000V voltage generator, a 999.5 ohm resistor, and a 1 ohm resistor, all in series. They are in a black box, and both ends of the 1 ohm resistor are bought out to two terminals on the black box. It is a trivial exercise to show that load that will develop the most power is approximately 1 ohms. At that point, the load voltage is 0.5V, and load power is 0.25W. Efficiency of the system (ie Pout/Pin) is 0.25/1000=0.025%. The o/c voltage is approximately 1V and internal dissipation is approximately 1000W, the s/c current is approximately 1A and internal dissipation is approximately 1000W.

I have another black box with a 1.0005V generator and a series resistance of 0.999000 ohms bought out to its two terminals. It produces exactly the same o/c current, but with internal dissipation of 0W, exactly the same s/c current with internal dissipation of approximately 1W, maximum power of approximately 0.25W in an approximately 1 ohm load for system efficiency of 50%.

Both of these networks have the same Thevenin equivalent circuit (in fact one is the equivalent circuit), they produce the same load current, load power, load voltage on the same load impedance, but their internal dissipation and efficiency is quite different.

The Thevenin equivalent circuit cannot be used to explain the internal dissipation or efficiency of a source network, but it can be used the explain the behaviour of the load network.

Owen

Sorry I ommited one comment:
The final Thevenin circuit is an idealization built with an ideal
voltage source in series with an ideal resistor. This new idealized
circuit It is a new born entity whose properties are now fully
described for these only two idealized circuit elements. These are the
virtues and the defects of reductionist models :>(

i don't care, i know that the superimposed voltage or current is
zero. from that i can calculate the power or energy anywhere i
want.

why does anyone care about 'energy' anyway, that is even worse to
think about in transmission lines than power. at least you can
measure, or at least calibrate your meters, in power units. have you
ever seen an amateur station that had an energy meter on their
transmitter? and isn't the term 'reflected energy' kind of an
oxymoron anyway? for energy to be reflected it has to be moving, so
isn't that just another word for power?

  I seem to recall this subject was written about in Communications
Quarterly. Now QEX.
Then debated in the next few issues in the Technical Conversations section,
and then
there may have even been a second article written as debate to the first.
  I thought the key term was conjugative match, but with a quick look all I
found was
a winter 1999 article more about tuners and cable "VSWR, Reflections, and
the Conjugate
Impeadance Match.
  Your subject "tube r-f amplifier using a tuned tank circuit (output
impedance)" was very
hotly debated over several issues. It was all above my ability, but I
gleaned a little from it.
  Someone with an ARRL membership can search the index and get the issues
```

with the articles
and all the technical correspondence.
Mike

"Richard Fry" <rfry@adams.net> wrote in message
news:3b9c7466-5bb5-46a7-a924-8897432a5365@j4g2000yqh.googlegroups.com...
It has been theorized that a circuit consisting of a Class C vacuum-tube r-f amplifier using a tuned tank circuit in its output network provides an operational �non-dissipative source resistance� of 50 ohms for energy present at the output connector of the transmitter.

However the information and measured data provided in the text excerpts below is not very supportive of that theory.

These excerpts discuss and show the effects of the energy entering a transmitter at its output connector by frequencies offset from the transmitter frequency.

There is direct applicability of the conclusions of the paper showing that the operational source impedance of the transmitter near/at the carrier frequency is much different than 50 ohms.

If it WAS a functional 50 ohms, then the termination provided to the transmission line for signals entering the transmitter by its output connector (whether on or off frequency) would not be present at the plate of the PA tube to react with the power being generated by the PA tube.

Rather the data leads to a logical conclusion that the operational source impedance of this configuration at the carrier frequency will be very low (approaching zero), when it is optimally tuned/adjusted to produce its rated output power.

Further discussion or comment is invited.

RF

From:

A STUDY OF RF INTERMODULATION BETWEEN FM BROADCAST TRANSMITTERS SHARING FILTERPLEXED OR CO-LOCATED ANTENNA SYSTEMS, by Geoffrey N. Mendenhall, P.E.*

II. INTERMODULATION AS A FUNCTION OF "TURN-AROUND-LOSS".
"Turn-Around-Loss" or "Mixing Loss" describes the phenomenon whereby the interfering signal mixes with the fundamental and its harmonics

within the non-linear output device. This mixing occurs with a net conversion loss, hence the term "Turn-Around-Loss" has become widely used to quantify the ratio of the interfering level to the resulting IM level. A "Turn-Around-Loss" of 10dB means that the IM product fed back to the antenna system will be 10dB below the interfering signal fed into the transmitter's output stage.

"Turn-Around-Loss" will increase if the interfering signal falls outside the passband of the transmitter's output circuit, varying with the frequency separation of the desired signal and the interfering signal. This is because the interfering signal is first attenuated by the selectivity going into the non-linear device and then the IM product is further attenuated as it comes back out through the frequency selective circuit.

"Turn-Around-Loss" can actually be broken down into the sum of three individual parts:
(1) The basic in-band conversion loss of the non-linear device.
(2) The attenuation of the out-of-band interfering signal due to the selectivity of the output stage.
(3) The attenuation of the resulting out-of-band IM products due to the selectivity of the output stage.

Of course, as the "Turn-Around-Loss" increases, the level of undesirable intermodulation products is reduced and the amount of isolation required between transmitters is also reduced.

The small portion of the interfering signal that is not reflected is what causes intermodulation products to be generated. Obviously the lower the output source impedance, the more complete the reflection (lower return loss), with the result being less production of intermodulation products.

III. EQUIPMENT PARAMETERS THAT AFFECT INTERMODULATION LEVELS.

The interfering signal must be coupled into the transmitter's output stage before the IM products are produced and the output level of the intermodulation products will be related to the interfering signal level.

The two parameters (outside of the filterplexing equipment) that most affect the interfering signal level into the transmitter's output circuit are the output loading and the circuit's frequency selectivity (loaded "Q"). These two parameters are interrelated because the degree of output loading will change the loaded "Q" of the output circuit while also affecting the return loss of the interfering signal looking into the output circuit.

"Output Return Loss" is a measure of the amount of interfering signal that is coupled into the output circuit versus the amount that is reflected back from the output circuit without interacting with the non linear device.

To understand this concept more clearly, we must remember that although the output circuit of the transmitter is designed to work into a fifty ohm load, the output source impedance of the transmitter is not fifty ohms. If the source impedance were equal to the fifty ohm transmission line impedance, half of the transmitter's output power would be dissipated in its internal output source impedance. The transmitter's output source impedance must be low compared to the load impedance in order to achieve good efficiency.

The transmitter therefore looks like a voltage source driving a fifty ohm resistive load. While the transmission line is correctly terminated looking toward the antenna (high return loss), THE TRANSMISSION LINE IS GREATLY MISMATCHED LOOKING TOWARD THE OUTPUT CIRCUIT OF THE TRANSMITTER (LOW RETURN LOSS). THIS MEANS THAT POWER COMING OUT OF THE TRANSMITTER IS COMPLETELY ABSORBED BY THE LOAD WHILE INTERFERING SIGNALS FED INTO THE TRANSMITTER ARE ALMOST COMPLETELY REFLECTED BY THE OUTPUT CIRCUIT.

VI. CONCLUSIONS

1. "Turn-Around-Loss" is a function of the particular non-linear device and the amount of loading on its output circuit.
2. "Turn-Around-Loss" increases as the interfering signal and the resulting IM products are moved away from the carrier and out of the output circuit passband.
3. "Turn-Around-Loss" will be least when the interfering signal is within the transmitter's passband.

The figure posted at the link below shows the measured data supplied with this paper.

http://i62.photobucket.com/albums/h85/rfry-100/TAL_Chart.gif

* Geoffrey Mendenhall presently is Vice President, RF Engineering at Harris Corporation Broadcast Division, and a recognized authority on transmitter system design. Harris Broadcast is one of the largest manufacturers in the world of AM/FM/TV broadcast transmitters, rated for power outputs up to 2,000 kW.

If you believe by your understanding of the clips you quoted from
Mendenhall that a conventional, single vacuum tube Class C r-f
amplifier provides a functional termination of 50+j0 ohms for energy
applied to the output connector of the transmitter, then please
explain why that termination allows such signals to reach the plate of
the PA tube -- whose non-linear characteristics created the
_measured_  r-f intermodulation products and other performance data
```

given in the Mendenhall paper I quoted.

In his food-for-thought article on forward and reflected power, Roy
(w7el) says: "So we can model a 100 watt forward, 50 ohm nominal
transmitter as a 141.4 volt (100 * sqrt(2)) RMS voltage source in
series with a 50 ohm resistance." He goes on to calculate power
dissipation in the source resistor.

You get exactly the same answers doing it my way but my way yields the additional information of exactly what happens to the energy components. When two wavefronts superpose to zero indefinitely, I would take that as proof of interaction and wave cancellation.

This is what invariably happens to the discussion. After being told that I am absolutely wrong about energy flow, I introduce the known laws of EM physics from the field of optics and prove that they provide exactly the same answers as a conventional RF analysis. After some discussion, it is asserted that the person (not only you) doesn't care and it doesn't matter anyway. W7EL says in his food-for-thought article, "I personally don=92t have a compulsion to understand where this power 'goes'."

A 1/4WL series matching stub is essentially the same function in concept as a 1/4WL thin-film coating on non-reflective glass. How the non-reflective glass works is perfectly understood and a 1/4WL series matching section works the same way. Why not glean some knowledge from the field of optics if it helps hams to understand "where the power goes"? Optical physicists were forced to track power density from the very start of their science because they didn't have the luxury of tracking the voltage and current.

The magnitudes of the voltages and currents in the above example are indeterminate. Can you (or anyone else) solve the problem without resorting to voltage and current calculations? I am just trying to get people to think outside of their rigid concrete voltage/current boxes.

Thanks for the concise and complete answer Walt. I have tucked it away
in my antenna notes for further use.

hams 'know' where the power goes, their swr meter tells them it goes
back to the transmitter!

why don't physicists working in optics calculate fields? the electric
and magnetic field models work just as well at those frequencies as
they do on hf. indeed, why don't optical physicists learn something
from rf designers and model their thin films with transmission lines!

> just for fun... explain why i can see that discontinuity between z01
> and z02 when i hook up my tdr.

That's easy, because it *physically exists in reality* with a voltage reflection coefficient of (Z02-Z01)/(Z02+Z01) =3D 0.5. It is related to the indexes of refraction in the field of optics from which the same reflection coefficient can be calculated.

The difficult question is: Exactly why doesn't that same physical reflection coefficient reflect half of the forward voltage when it is Z0-matched during steady-state?

The answer is that it indeed does reflect 1/2 of the forward voltage during steady-state but that wavefront interacts with 1/2 of the reflected voltage returning from the mismatched load which is equal in magnitude and 180 degrees out of phase. In this case, superposition of the two waves results in wave cancellation (total destructive interference). The energy components in those two waves are combined and redistributed back toward the load as constructive interference in phase with the forward wave from the source. That's where the reflected energy goes.

That's why the s-parameter analysis theory could be important to hams. By merely measuring the four reflection/transmission coefficients (s11, s12, s21, s22) one learns the basics of superposition. S-parameter analysis was covered in my 1950's college textbook, "Fields and Waves in Modern Radio", by Ramo and Whinnery (c)1944. I don't know how or why the younger generation missed it.

Purposefully, the numerical values of Z01 and Z02 are not given and
unknown. The answer to the problem would be the same if Z01=3D50 and
Z02=3D150, or if Z01=3D100 and Z02=3D300, or an infinite number of other
combinations. Please tell me how you can calculate an absolute voltage
when Z0 is an unknown variable?

And a mere two sentences back one find Roy writing:
"I make no claim that the model circuit represents what=92s going on
inside the transmitter. For one thing, a real transmitter will
typically be more efficient than the model. However, if measurements
and observations are limited to the outside of the transmitter,
the model is very good (within the non-shutdown range). Although
a real transmitter won=92t contain the model=92s resistance as a
resistor, we will take a look at the model resistor=92s dissipation
to see how it interacts with the =93reverse=94 power."

Was your disingenuity deliberate?

...Keith

because they use the newer 'fields and waves in communication
electronics' by ramo, whinnery, and van duzer that uses reflection
coefficients and calculates voltages, currents, electric and magnetic
fields.

the same way you calculate the power to be zero watts.  no need to
know the z0 if the voltage is zero.

'Unusual'? Certainly not unexpected once one thinks about it. For a given controlled power, the minimum dissipation in the controlling device will occur when the minimum voltage occurs at the time of maximum current, and vice versa, i.e. the voltage and current in the load are in phase, or equivalently, the load impedance is resistive.

I would expect this to be a fundamental characteristic, and not just for VHF amplifiers.

The 60Hz folk are trying to achieve the same result as they strive for a power factor of 1.

...Keith

Hello Owen,

I fully agree with you. When I am doing power electronics, I show myself the instantaneous current*voltage plot, and the averaged integral. The last one shows the dissipated power, the first one tells me where I have my losses (and also what I have to change to reduce the overall loss or reduce component stress).

Regarding the class C output impedance issue, I updated my simulations with a 3.6 MHz output stage with a 6146 tube and real class C operation.

You can almost get every impedance you want, also the conjugated match condition, but you need to do many simulations to find that point. With hours of time, I couldn=92t get closer to an output VSWR of 1.58 with 79% efficiency. I know you can get closer, but at his moment I cannot provide you a spice file as I don=92t have it anymore and I also dropped orcad long time ago. .

The smallest change in output loading or drive level results in significant change of output impedance. So take an arbitrary class C amplifier, measure its output impedance and it will very likely be way off the intended load (in my example 3500 Ohm).

If you want to use load change method with some different resistive loads, you should make phase measurements to get valid results, as you don't know whether you amplifier has real or complex output impedance.

For the class C amplifier I changed the drive by +0.36 dB, resulting in an increase of plate efficiency from 79% to 80%, but the output VSWR changed from 1.58 to 3.6. Also reduction of input drive gives significant change in VSWR (magnitude and phase).

I hope that people will reproduce some of the simulation themselves to develop a solid opinion on their own.

Best regards,

Wim

Would you please respond in your own words directly to my
previous statement (repeated below)?

If you believe by your understanding of the clips you quoted from
Mendenhall that a conventional, single vacuum tube Class C r-f
amplifier provides a functional termination of 50+j0 ohms for energy
applied to the output connector of the transmitter, THEN PLEASE
EXPLAIN WHY THAT TERMINATION ALLOWS SUCH SIGNALS
TO REACH THE PLATE OF THE PA TUBE -- whose non-linear
characteristics created the _measured_ r-f intermodulation products
and other performance data given in the Mendenhall paper I quoted.

On Sun, 13 Jun 2010 10:03:40 -0700 (PDT), Keith Dysart <keith.dysart@gmail.com> wrote:

>'Unusual'? Certainly not unexpected once one thinks about it.

Hi Keith,

The "unusual" was lost in the ellipsis that I will reveal:
"... The highest efficiency operating point does not exactly coincide with the lowest plate current because the power output continues to rise for a while on the inductive side of resonance coming out of the dip in the plate current. ..."

Continuing, Mendenhall presents the problems of trade-offs between what would seem to be maximum power for worsening characteristics in performance - the goal is what he calls minimizing synchronous AM versus Efficiency.

Synchronous AM is a problem that can be introduced by measurement equipment, as Mendenhall relates: "The input impedance of the envelope detector must provide a nearly perfect match ... 30dB return loss ... to the sampling line."

This sidebar relates to what Owen characterized as "Usability" where I have recited the objective technical specification to reduce the subjectivity of the term.

There's more that could be said, but I am waiting to see if Richard is willing to subscribe to his own reference's writings. If not, and Mendenhall doesn't mince words on the topic, then as Perry Mason would observe "The D.A. is impeaching his own witness!"

I've always loved Perry Mason.

I responded to you some 20 minutes before you posted, and now await your response.

Also please comment on whether or not a Class C amplifier operating on
a linear portion of its transfer curve will function as a linear
amplifier.

Hi Richard,

I conform to Mendenhall to the specific statement I responded to.

>If you believe

What I believe has been succinctly laid out in my subscribing to
Mendenhall's explicit statement.

>THEN PLEASE EXPLAIN WHY

I don't see that elaboration is going to improve what has been presented.

Yes, it is a difficult concept that many struggle with and few have had experience in making a sufficiently accurate determination of. Consult Walt's 333 line posting and examine how experience comes to bear and through my recitations reveal the dovetail fit to theory.

The Only Explanation Possible:

Here's a modest proposal, Mendenhall constructed a power amplifier that is within the technical grasp of many here to achieve at a modest workbench. The design is quite spartan. The design is quite understressed (there is nothing "forcing" a conclusion). The design conforms to all engineering standards.

Build your own. [It feels strange to have to offer that option to a group of Hams.]

Having this amplifier before you, observe all the variables, play with them. Measure their impact on NOhms. Account for the heat with direct measurement and note what does not conform to convention.

When that is finished the real work begins. Calibrate your tools and repeat this for accuracy.

So your subscription to your own authority is contingent upon me?

I'm flattered.

>Also please comment on whether or not a Class C amplifier operating on
>a linear portion of its transfer curve will function as a linear
>amplifier.

"If the amplifier is tuned exactly to resonance, the plate load
impedance will be purely resistive and the load line will be linear."

I would note that the bulk of his paper concerns frequency products -
something the bears quite intimately upon linear operation.

Your question is rather opaque in that the appearance of subtext is
undoubtedly bound up in the term "linear" which Mendenhall has already
employed within the norms of amplifier design.

How linear is linear? Give me a technical criteria (subjectivity
abounds and is not very informative except for statements of fashion).
Express the least departure from a line response in percent that you
accept as being linear. If it exceeds Mendenhall's design or
commercial product, then I am afraid you won't be satisfied with any
answer.

On Jun 13, 1:20=A0pm, Richard Clark <kb7...@comcast.net> wrote:

> How linear is linear? =A0Give me a technical criteria...

A truly linear device does not produce r-f intermodulation products when signals of different frequencies are applied to it at the same time.

For many practical uses a linear device does need to be perfectly linear. Let's say that the IM products need to be only - 20 dB w.r.t the lowest amplitude value of the various input frequencies. The Mendenhall paper I quoted conclusively shows that even such nominally linear performance is not an attribute of Class C vacuum tube r-f amplifiers -- especially at, and near the center frequency of the PA output tuning/matching network.

That Mendenhall paper also shows that such r-f amplifiers do not present a functional, 50+j0 termination to r-f energy entering via the tx output connector. That is the reason why such energy is present in the PA plate circuit, giving rise to r-f intermodulation and/or changing the power dissipation there.

Medenhall's paper shows "RF spectrum showing distortion products" that are 30dB down.

His statement: "If the amplifier is tuned exactly to resonance, the plate load impedance will be purely resistive and the load line will be linear." is attached to that linearity which is greater than you expect.

To Richard Fry,

Richard, it appears that you have ignored my post where I reported data that proves the output resistance of Class B and C RF amps is non-dissipative. Have you reviewed or ignored my reference to Chapter 19 in Reflections 3, or the combined sections of that chapter that appear in my web page at www.w2du.com that uses an example from Terman's Radio Engineers Handbook? If you haven't yet reviewed it I urge you to do it, and then if you disagree with my measured data I'd like for you to explain the reason for your disagreement.

Walt, W2DU

Not near the resonant frequency of the output tuning/matching network.

He shows as little as 5 dB at 0.8 MHz offset of the external signal
from the carrier of that tx. It would be less than 5 dB for lesser
separations.

The reason that the IM performance improves for greater frequency
separations is related to the r-f bandwidth of the output network --
not the "linear" operating characteristics of the PA, or that a 50+j0
ohm load is seen by the external energy reaching the tx output
connector.

[Sorry for being a little late to the party, but I was off newsgroups most of this week.]

This thread had some discussion of adapters and I want to share my bad experience with some low-cost items, proving, once again, that you get what you pay for.

I am testing all my adapters and discarding some because the assemblies are pulling apart with very little force. One manifestation: tightening the threaded ring on a PL-259 (either cable end connector or adapter) and having the ring just continue all the way on, separating from the connector body.

One test for a future failure has been any lack of smoothness when I rotate the ring while tugging it gently. If it binds, rather than turning smoothly in my hands, it's going to fail. Also, some of the cheap connectors are press-fit together very poorly; they pull apart with only a few pounds of pull.

Most of my early exposure to coax connectors was in and around the US Navy, where reliable connectors are the rule, so I was a spoiled child.

PL-259's I can handle.
BNC's drive me nuts trying to get a good connection.
I gave up and just buy my cables now.
Bill

I know your conclusion, thanks Walt.

The impedance of a perfect transmission line also is non-dissipative, but that does not change the power dissipated in a termination of that transmission line equaling its Zo.

Do you agree that the Mendenhall paper I have quoted shows that the source impedance of an operating Class C vacuum tube PA and its output tuning/matching network designed for a 50 ohm load is not, by itself, a functional 50+j0 ohms?

RF

> definition of 'virtual impedance' in the ieee dictionary?

"The IEEE Dictionary" has no such definition. Those are my words adopted from "Reflections", by Walter Maxwell, and designed to differentiate between the (A) and (B) definitions of "impedance" in "The IEEE Dictionary". Calling the V/I (B) definition of impedance, "virtual", is much more descriptive than calling it "the (B) definition".

Walt is arguing that the impedance of an RF source is "non-dissipative". Ratios of V/I are non-dissipative if they exist devoid of an impedor. Walt adopted the word "virtual" from the optics "virtual image". It is an image that is not really there in reality. A virtual impedance would therefore be the image of an impedor that is not really there.

I'm not hung up on the word "virtual". What adjective would you use to differentiate between a dissipative impedor and a V/I non-dissipative impedance? I am not trying to be difficult - just trying to

communicate. I'm willing to adopt any convention that you suggest for
the duration of this discussion.

On Jun 11, 12:09=A0pm, Roy Lewallen <w...@eznec.com> wrote:

> Can you write an equation giving the supposed dissipation caused
> by "reflected power" as a function of transmission line length?

I'll just quote the following from Chapter 24-11 of REFERENCE DATA FOR
RADIO ENGINEERS, 1975 Edition:

QUOTE
A load of 0.4-j2000 ohms is fed through a length of RG-218/U cable at
a frequency of 2.0 MHz. What are the input impedance and efficiency
for a 24-foot length and a 124-foot length?

(Omitting the number crunching shown...)

Tabulating the results,

Length (feet)	Input Impedance (ohms)	Efficiency (%)	Loss (dB)
24	0.106-j95	1.1	19.6
124	1.8+j55	0.03	35

The considerably greater loss for 124 feet compared with 24 feet is because the transmission passes through a current maximum, where the loss per unit length is much higher than at the current minimum.
END QUOTE

As the input Z for each of these lengths is not the same as their 0.4-j2000 ohm termination, this shows the dependence of the performance of such systems on the electrical lengths of the transmission line in use.

I realize we have strayed into the real world here, because RG-218/U transmission line is not lossless even when perfectly matched at both ends.

In answer to the question you directly asked, yes. But that says nothing of whether such a transmitter, in the general case, is well represented by a Thevenin equivalent circuit with Zeq=50+j0.

As you know, there is a proposition that a transmitter "designed/adjusted for, and expecting a 50 + j 0 ohm load" can be well represented by a Thevenin equivalent circuit and naturally has Zeq=50+j0. However, that proposition is easily proven wrong by valid experiments in the real world, and those of us who have done such experiments are disinclined to accept the proposition.

>
> IOW, if the net output power of such a transmitter (which equals that

> you expect the reason for that to be related to "reflected power?"

Average power at the transmitter terminals is given by the average value of the instantaneous product of v and i over time. There is no need for "net" in the calculation. The average power delivered by the transmitter will depend on the load impedance (ie the complex ratio of v/i) at its load terminals, but that dependence is not well predicted in the general case by a Thevenin equivalent circuit.

I gave a link to a simple experiment to test Zeq of a tx, and that uses equipment found in most ham shacks. The article is at http://vk1od.net/blog/?p=1028 .

The author acknowledges that loss under standing waves is not uniform, that in this case, it is higher in the region of a current maximum. That is simply explained the I^R effects on the conductors (which account for most of the loss in most practical coax cables at that frequency).

If you treated the forward and reflected waves as travelling independently, and each attenuated by the matched line loss characteristic of the line, you would get a different (and incorrect) result. It happens that we sometimes make that approximation, and under many practical scenarious, it gives a result with acceptable error, it is nevertheless less accurate because the model is poorer.

Yes, it does, and not simply on the VSWR as often inferred.

But that does not change the transmitter's behaviour in its output power being sensitive the the impedance at its load terminals, however that impedance is derived, and your response has not answered Roy's question, well at least in my mind.

>
> I realize we have strayed into the real world here, because RG-218/U

Indeed, under some circumstances, the line can have less loss when not perfectly matched. Yes, throw those treasured graphs of ExtraLoss vs VSWR away, they depend on assumptions not usually stated.

Cases similar to the example you quoted can be solved using TLLC at http://www.vk1od.net/calc/tl/tllc.php . An interesting case is to explore the loss in 1m of RG58C/U at 3.6MHz with 50+j0, 500+j0, and 5+j0 loads. The latter two are VSWR=10, but have quite different loss. The first two cases demonstrate that VSWR does not necessarily cause extra loss (compared to the matched line case).

Owen

Yes it is OK I am not saying your article use 1/4, In a previous post
I said with 1/8 lambda TL, results support your idea of Pref
dissipating on Rs (is correct my interpretation of your idea?).
Yesterdey I posted results calculated for a 1/4 lambda TL to comparing
both ponting to 1/4 lambda results did not agree with a Pref
dissipating on RS.
Then, I thought you are not intending generalize the very common
notion of.Pref returnig to generator but seem to me you are
hypothesizing there are different mechanisms dealing with Pref
depending of the line length. Is It OK?

(Meanwhile I will take a look at the new thread to look if I can find
exactly what is the heart of this question ;>)  )

what is an 'impedor' in this context? that is a relatively rarely
used term in circuit and wave analysis, but is generically defined as
anything that has an impedance. that doesn't seem to fit your
definition though if you can qualify an impedance as non-dissipative
if they don't have one.

the ieee dictionary qualifiers of dissipative and non-dissipative seem
adequate to me. no need to make up any other terms or qualifiers.

Hopefully, the same IEEE Dictionary definition as any other context:
"impedor - a device, the purpose of which is to introduce impedance
into an electric circuit." Note that it has a material existence.

> the ieee dictionary qualifiers of dissipative and non-dissipative seem
> adequate to me. =A0no need to make up any other terms or qualifiers.

OK, I will change "virtual impedance" to "non-dissipative impedance"
although if the resistance is zero, that still doesn't solve the
semantic problem. The word "virtual" as used by Walter Maxwell over
the past half-century conveys the meaning as well as any other words,
IMO.

The fact remains that a dissipative impedor is something that exists
in the material world and can cause an outcome. A non-dissipative
impedance is a *result* of a superposed V/I ratio, not a cause of
anything.

Roy once challenged me to detect the difference between a 50 ohm
antenna and a 50 ohm dummy load. I said, "Simple, use a field strength
meter."

Yes, a 1/8WL line is a *SPECIAL CASE* where zero interference exists.
In the power density equation:

Ptot =3D P1 + P2 + 2*SQRT(P1*P2)*cos(A)

if A =3D 90, then cos(A) =3D 0 and there is no interference term and no interference. When you go to a 1/4WL line, it is no longer a special case where cos(A)=3D0 and I have not published anything on my web page about that condition.

Hello, here we are...! :>)

At the risk of na=EFve and conciliatory I still thinking that to some extent this is a problem of "same cat seen from different points of view".

What if the question is formulated in terms apart, for example =3D> generator responses to load differences, and by what mechanism a transmission line transforms impedances to presents to the generator those different loads?
In that formulation I think there are room to simple, basic, and understandable electrical laws to account for generator behaviour and TL travelling waves interference phenomenom to account for Z transformings.

From my perspective your main differences are reducible

wrote:

>you can qualify an impedance as non-dissipative

It's called reactance.

There are certainly some contortions that have evolved from an argument that the source lacks the ability to dissipate.

Impedance = (R � jX) Ohm

This is well known by all and yet it seems unsatisfactory and impossible to measure in a Tube even when R is exhibited both by measurement and by heat - something that by all normal accounts is evidence of dissipation. That same heat seems to be unaccountable because it's non-linear?   If you use this heat on an ice cube, do you get harmonics? Even or odd?

If it doesn't dissipate it must be because it has NOhms. If we embark further on this mysterious Load Conjugation with a loss-less resistor, what would we see for the Load Objurgation formula?

rraaZ = (Rr � iR � jX) NOhm

We must now have a Nimpedance measured along a second (hither too unreported) imaginary axis. I can imagine the dawn of the new Photon Ninterferences that will emerge from this.

KEWEL !

Using the same transmitter originally "designed/adjusted
for, and expecting a 50 + j 0 ohm load"?

I don't suppose this anecdote has any data behind it, does it?

The easy proof has yet to wrong Walt's proposition - or did he state
something to the contrary my reading that he represented a Thevenin
equivalent circuit in the first two steps of his recent report?

> I don't suppose this anecdote has any data behind it, does it?

I have performed many tests on many radios. One documented example is at http://vk1od.net/blog/?p=1045 .

The concept is dealt with in more depth at http://vk1od.net/blog/?p=1028 .

Thing is that those supporting the Zeq=50 proposition, declare that since the test showed that Zeq (or Zs in the article) is not approximately 50 +j0, then the radio isn't "designed/adjusted for, and expecting a 50 + j 0 ohm load".

Thing is that you cannot use the measured VSWR to reasonably predict the reduction in power output (Mismatch Loss) on many HF ham radio transceivers.

I invite you and others to perform the same test. You will realise that one, or even 100 supporting tests do not prove the proposition, but one valid test to the contrary is damaging.

Owen

not always.  there is a non-dissipative resistance.  a lossless
transmission line has a pure real impedance, but no dissipation.

define "mismatch loss".

and why would you expect that vswr is a good predictor of power
output?  other than radios that use vswr sensing circuits to reduce
power output to protect their output transistors?

and why would anyone expect the output of an rf amplifier to be linear
except in a narrow range of selected loads and tuning conditions?
thats just plain crazy!

Mismatch loss is the reduction in power available in a mismatched load compared to a matched load. Mismatch Loss can be calculated in linear systems with Zs purely real as 1-rho^2. I wrote some notes at http://vk1od.net/blog/?p=659 which discusses the underlying assumptions.

>
> and why would you expect that vswr is a good predictor of power

The concept of Mismatch Loss is a sound one, but application to a typical ham transmitter is flawed because the underlying assumptions are violated
.

The basic argument revolves around what math shortcuts can be used to solve a particular problem vs what is actually happening in reality according to the accepted laws of physics. I agree one doesn't

necessarily need to understand the laws of physics to solve a problem
but one should probably know enough physics to recognize when those
laws of physics are being violated by one's argument.

sure, if you properly apply the telegrapher's equations and the thevenin equivalent methods. The real problem is that if you try to do that for most amateur radio transmitters the source impedance is not linear, and even worse may be time varying, which renders the thevenin equivalent source substitution invalid.

Note though that in real world cases you need to use the full set of equations, usually called by engineers the 'general transmission line equations'. beware, some places may over simplify the telegrapher's equations which may make them invalid in some cases. The Telegrapher's equations (http://en.wikipedia.org/wiki/Telegrapher%27s_equations), are often considered a subset of the 'General transmission line equations (http://en.wikipedia.org/wiki/Transmission_line) that are taught in distributed circuits and fields and waves courses in engineering schools.

rather than worrying about basic physics, the real problem here is
that analysis of a non-linear circuit is being attempted using
techniques that are only valid for linear circuits.

Antenna is a quarterwave vertical with quarterwave radials.

There is a difference in operation between transmit and receive modes.

In receive mode, an incident plane wave is exciting the radials. The
induced currents are a function of angle around the antenna. A system of
radials imperfectly reflects the incident wave, and the reflected wave is
hard to calculate.

In transmit mode, the antenna base is driven by the source. The currents in the radial system are symmetrical around the antenna, NOT a function of angle, so they produce no net radiation, but do affect the input impedance.

In receive mode, the current induced in each radial is related to the direction of the incoming wave. For example, radials closest to the incoming wave experience the strongest field.

Does the radiation pattern override the direction of the incoming wave? The radiation pattern is omnidirectional or circular.

I suspect that the radiation pattern takes the incoming wave and spreads it evenly around the antenna, forming an electromagnetic field that is the same as the radiation pattern.

Even if parts of the antenna experience the strongest field due to the direction of the incoming wave, the radiation pattern means that the field is symmetrical. Is this correct?

A uniform radiation pattern means that the electromagnetic field is spread evenly around the antenna irrespective of which direction the wave is being received. Is this true?

Miguel, I don't think there is much disagreement about things that are easily measured, like voltage and current. One solution to the telegrapher's equations involves forward and reflected waves of voltage and current. The conventional way of handling power (energy/unit-time) is to use the voltages and currents to calculate the power at certain points of interest. The telegrapher's equations do not tell us *why* the power is what it is and the energy is where it is. To obtain the why, one must study the behavior of electromagnetic waves. How does the energy in electromagnetic waves behave? The telegrapher's equations and Thevenin source do not answer that question.

For instance: Most readers here seem to think that the only phenomenon that can cause a reversal of direction of energy flow in a transmission line is a simple EM wave reflection based on the reflection model. When they cannot explain what is happening using that model, they throw up their hands and utter crap like, "Reflected wave energy doesn't slosh back and forth between the load and the source". But not only does it "slosh back and forth", it sloshes back and forth at the speed of light in the medium because nothing else is possible.

These are the people who have allowed their math models to become their religion. They will not change their minds even when accepted technical facts are presented. One response was, "Gobblydegook". (sic)

There is another phenomenon, besides a simple reflection, that causes reflected energy to be redistributed back toward the load and that is wave cancellation involving two wavefronts. If the two wavefronts are equal in magnitude and opposite in phase, total wave cancellation is the result which, in a transmission line, redistributes the wave energy in the only other direction possible which is, surprise, the opposite direction. This is a well known, well understood, mathematically predictable phenomenon that happens all the time in the field of optics, e.g. at the surface of non-reflective glass. It also happens all the time in RF transmission lines when a Z0-match is achieved.

Using the s-parameter equations (phasor math) at a Z0-match point in a transmission line:

b1 =3D s11*a1 + s12*a2 =3D 0 =3D reflected voltage toward the source
Square this equation to get the reflected power toward the source.

These are the two wavefronts that undergo total wave cancellation, i.e. total destructive interference.

b2 =3D s21*a1 + s22*a2 =3D forward voltage toward the load
s22*a2 is the re-reflection. Square this equation to get the forward power toward the load.

If one squares both of those equations, one can observe the interference terms which indicate why and where the energy goes. All of the energy in s11*a1 and s12*a2 reverses direction at the Z0-match and flows back toward the load. All the things that Roy is confused about in his food-for-thought article on forward and reflected power are easily explained by the power density equation (or by squaring the s-parameter equations).

Ptot =3D P1 + P2 + 2*SQRT(P1*P2)*cos(A)

It has been theorized that a circuit consisting of a Class C vacuum-tube r-f amplifier using a tuned tank circuit in its output network provides an operational =93non-dissipative source resistance=94 of 50 ohms for energy present at the output connector of the transmitter.

However the information and measured data provided in the text excerpts below is not very supportive of that theory.

These excerpts discuss and show the effects of the energy entering a transmitter at its output connector by frequencies offset from the transmitter frequency.

There is direct applicability of the conclusions of the paper showing that the operational source impedance of the transmitter near/at the carrier frequency is much different than 50 ohms.

If it WAS a functional 50 ohms, then the termination provided to the transmission line for signals entering the transmitter by its output connector (whether on or off frequency) would not be present at the plate of the PA tube to react with the power being generated by the PA tube.

Rather the data leads to a logical conclusion that the operational source impedance of this configuration at the carrier frequency will be very low (approaching zero), when it is optimally tuned/adjusted to produce its rated output power.

Further discussion or comment is invited.

RF

From:

A STUDY OF RF INTERMODULATION BETWEEN FM BROADCAST TRANSMITTERS SHARING FILTERPLEXED OR CO-LOCATED ANTENNA SYSTEMS, by Geoffrey N. Mendenhall, P.E.*

II. INTERMODULATION AS A FUNCTION OF "TURN-AROUND-LOSS".
"Turn-Around-Loss" or "Mixing Loss" describes the phenomenon whereby the interfering signal mixes with the fundamental and its harmonics within the non-linear output device. This mixing occurs with a net conversion loss, hence the term "Turn-Around-Loss" has become widely used to quantify the ratio of the interfering level to the resulting

IM level. A "Turn-Around-Loss" of 10dB means that the IM product fed back to the antenna system will be 10dB below the interfering signal fed into the transmitter's output stage.

"Turn-Around-Loss" will increase if the interfering signal falls outside the passband of the transmitter's output circuit, varying with the frequency separation of the desired signal and the interfering signal. This is because the interfering signal is first attenuated by the selectivity going into the non-linear device and then the IM product is further attenuated as it comes back out through the frequency selective circuit.

"Turn-Around-Loss" can actually be broken down into the sum of three individual parts:
(1) The basic in-band conversion loss of the non-linear device.
(2) The attenuation of the out-of-band interfering signal due to the selectivity of the output stage.
(3) The attenuation of the resulting out-of-band IM products due to the selectivity of the output stage.

Of course, as the "Turn-Around-Loss" increases, the level of undesirable intermodulation products is reduced and the amount of isolation required between transmitters is also reduced.

The small portion of the interfering signal that is not reflected is what causes intermodulation products to be generated. Obviously the lower the output source impedance, the more complete the reflection (lower return loss), with the result being less production of intermodulation products.

III. EQUIPMENT PARAMETERS THAT AFFECT INTERMODULATION LEVELS.

The interfering signal must be coupled into the transmitter's output stage before the IM products are produced and the output level of the intermodulation products will be related to the interfering signal level.

The two parameters (outside of the filterplexing equipment) that most affect the interfering signal level into the transmitter's output circuit are the output loading and the circuit's frequency selectivity (loaded "Q"). These two parameters are interrelated because the degree of output loading will change the loaded "Q" of the output circuit while also affecting the return loss of the interfering signal looking into the output circuit.

"Output Return Loss" is a measure of the amount of interfering signal that is coupled into the output circuit versus the amount that is reflected back from the output circuit without interacting with the non linear device.

To understand this concept more clearly, we must remember that although the output circuit of the transmitter is designed to work into a fifty ohm load, the output source impedance of the transmitter is not fifty ohms. If the source impedance were equal to the fifty ohm transmission line impedance, half of the transmitter's output power would be dissipated in its internal output source impedance. The transmitter's output source impedance must be low compared to the load impedance in order to achieve good efficiency.

The transmitter therefore looks like a voltage source driving a fifty ohm resistive load. While the transmission line is correctly terminated looking toward the antenna (high return loss), THE TRANSMISSION LINE IS GREATLY MISMATCHED LOOKING TOWARD THE OUTPUT CIRCUIT OF THE TRANSMITTER (LOW RETURN LOSS). THIS MEANS THAT POWER COMING OUT OF THE TRANSMITTER IS COMPLETELY ABSORBED BY THE LOAD WHILE INTERFERING SIGNALS FED INTO THE TRANSMITTER ARE ALMOST COMPLETELY REFLECTED BY THE OUTPUT CIRCUIT.

VI. CONCLUSIONS

1. "Turn-Around-Loss" is a function of the particular non-linear device and the amount of loading on its output circuit.
2. "Turn-Around-Loss" increases as the interfering signal and the resulting IM products are moved away from the carrier and out of the output circuit passband.
3. "Turn-Around-Loss" will be least when the interfering signal is within the transmitter's passband.

The figure posted at the link below shows the measured data supplied with this paper.

Well, that's certainly one problem but I was talking about linear circuit analysis. When will the effects of linear wave cancellation be understood by the ham radio community?

Walt seems to have sidestepped the non-linear source problem by defining the "source" as the first point in the system at which the source signal becomes linear after filtering. He seems to draw a system box boundary through that point and labels that signal, "the source". The ratio of voltage to current at that point is, by definition, the source impedance. That approach sure does simplify things.

The output of a class-C amp is weighted with odd harmonics. The system is obviously mismatched at the odd harmonic frequencies.

they won't because waves don't 'cancel' any more than they 'interact'
in linear systems.  they do superimpose which gives the illusion of
cancellation and intensification.  the worst thing causing amateurs
problems is using power and trying to think about energy... neither
one is a linear phenomenon, but they are often treated as such because
of some simple cases where you can add and subtract powers... when
```

someone who doesn't understand the restrictions fully tries to use powers on more general cases they get in trouble. that is why it is always better to use current or voltage where you can (in many more cases) add them linearly and be correct. of course then there are those who try to push even those restrictions back into non-linear realms, like amplifiers, and get into even more trouble.

yeah, lots of words that say things kind of related, but more confusing than useful for what is really being discussed.

what is so hard about stating:
1. tubes and transistors are non-linear devices
2. tank circuits and other output matching systems TRY to make them appear more linear to the outside world, but are not perfect.

any circuit that has non-linear characteristics will have a response that is not like a simple resistance. such systems must be modeled using appropriate non-linear techniques to get the full and proper response characteristics. An APPROXIMATION may be used in many systems that allows an equivalent simple impedance representation, but often only over SMALL ranges of voltage/current or frequency. The problem appears to be in this discussion that some people have used

```
this small signal approximation to derive results in a domain where it
is not applicable and are drawing the wrong conclusions.

Here's proof otherwise:
```

b1 =3D s11*a1 + s12*a2 =3D 0 =3D reflected voltage toward the source

The permanent result is that reflected voltage and power equal zero?
How can that possibly be an illusion?

(b1)^2 =3D (s11*a1 + s12*a2)^2 =3D 0 =3D reflected power toward the source.
s11*a1 is not zero, s12*a2 is not zero, they are equal in magnitude and opposite in phase.

What happens to the non-zero (s11*a1 + s12*a2)^2 power? The answer to that question is what a lot of people are missing.

Those two reflected wavefronts have interacted destructively and canceled. That destructive interference energy is redistributed back toward the load as constructive interference energy in the other s-parameter equation.

b2 =3D s21*a1 + s22*a2 =3D forward voltage toward the load

(b2)^2 =3D (s21*a1 + s22*a2)^2 =3D forward power toward the load

Doesn't the fact that reflected energy cannot be traced using only the wave reflection model indicate that there is something missing from that procedure?

Hello Richard Fry,

First, I use your last name also to avoid confusion with Richard
Clark.

As you may know, I have also doubts about the conjugated match issue.
So I am happy with this posting. It is not that I dispute the
conjugated match condition itself, but whether or not the conditions
are met. In my opinion, required conditions aren't met in many cases,
so output impedance of many amplifiers is not equal to the load
resistor.

To avoid discussions about measurements and traceable measurement
instruments/procedures, I did some simulations on a valve amplifier
and a class C mosfet circuit (that actually isn't operating in class C
mode). Everyone can do these simulations at their own PC en get an
opinion. I also described the difference frequency method that is
easily implemented in simulation and gives the output VSWR almost
directly without complex calculus. The link is: www.tetech.nl/divers/PA_imp=
edance.pdf.

Except for the condition of matching to maximum power output given
certain drive, all output VSWR of the amplifiers is far from expected
load impedance. Just a little voltage saturation (for example to get
better efficiency) did drop the plate impedance below the required
load impedance (voltage source behavior). When reducing the drive, the
plate impedance rises rapidly above the load impedance (current source
behavior).

So power entering the output of the amplifier will mostly be reflected
back into the cable, unless you specially design for output impedance.
I know, this is disputed by some members of this group, but therefore
I did the simulations and presented the results.

I specially took "amateur" examples to avoid comment that I only use "exotic" examples. I did not copy results from professional activities, so I will not run into problems. The circuits are simple to ease reproduction in any spice based simulator.

I dispute:
"If the source impedance were equal to
the fifty ohm transmission line impedance, half of the transmitter's
output power would be dissipated in its internal output source
impedance."

A real class C amplifier with very small conduction angle has efficiency > 50% when optimally tuned. When it operates at the transition of current/voltage saturation is can show 50 Ohms output impedance for very small change in load impedance. But as soon as the load mismatch is above about VSWR =3D 1.05=851.1, output VSWR/impedance of the amplifier changes rapidly. So practically spoken, most high efficient amplifiers have high output VSWR (or bad Return Loss), but theoretically it can be 50 Ohms (for example). If there are doubts I will add a special simulation example for this.

Best regards,

Wim

Would that not be evidence that the amplifier source impedance
necessarily is lower than the load impedance?

For some additional input -- I have taken part in factory tests of
high-power Class C single-tube/tuned cavity FM broadcast transmitters
driving 50-ohm test loads measured to have < 1.03VSWR, showing a DC
input to r-f output efficiency of the PA to be in excess of 80% --
including the loss in the harmonic filter. Load power was measured
using calorimetric methods. In fact, 80% PA efficiency is the
published spec for this transmitter line as long as load VSWR relative
to 50 ohms is 1.7:1 or less (any phase angle).

Those results don't appear to be fitting very well with the idea that
the tx source impedance can be ~50 ohms for loads with low VSWR.

No, not at all.  It is important to realize that a real source is NOT
necessarily like either the Thevenin or the Norton equivalent.  The
Thevenin and Norton equivalents, when discussed in any respectable
text, will be noted to behave exactly like any other real linear
source with respect to the load, but NOT necessarily with respect to
the source itself, and in particular with respect to source efficiency
and dissipation.

For example:  I can, at least theoretically, build a switching power
supply (a source) which measures its output voltage and current and
adjusts the voltage down by 50 volts for each amp that's drawn from
it.  Because it is always operating as a switching supply with very
high efficiency, even when it's loaded so the output voltage is half
the zero-current output voltage, it's not behaving internally like a
Thevenin equivalent, even though it has a 50 ohm output resistance.

As Wim says, the conjugate-matched output impedance is guaranteed only over a very narrow range of conditions. Specifically, it's for the condition where you can't adjust the load impedance in any direction without lowering the power delivered to the load. For a power output stage with a tank that can tune both resistance and reactance (such as a pi network), that should be equivalent to adjusting the pi network to maximize the power delivered to the load with a particular fixed set of bias/drive conditions for that output stage.

But why would I necessarily want to operate the output stage that way? What if I'm providing enough grid drive and plate voltage to my 6146 that it's capable of outputting 150 watts (class C), but if I were to tune up the output matching network to get that much output power, the tube's life would be significantly shortened because the plate dissipation would be too high? What if I'm operating it class AB, with low enough drive so that the plate voltage and current change only by small percentages?

Or to me, more to the point: why would I care what the source impedance of my transmitter is? With the power at the wall outlet in my house, I expect a nearly constant voltage, and have no intention of loading it with a "conjugate match." I don't know WHAT its source resistance is, exactly, but I know it's much lower than the loads I put on it. With an electric motor, I have no intention of putting a load in excess of the motor's rating on it, for fear of burning up the motor, even though I know that for short periods the motor can deliver quite a bit more output power than its nameplate rating. With a switching power supply, same thing: I don't load it to the point of significant drop in output voltage. All I want from ANY of these, including the RF power amplifier, is the ability to deliver the expected power to the rated load.

In the instrumentation systems I deal with professionally, there are times I care very much about source impedance. With respect to ham transmitters and power amplifiers, though, I just can't get excited about caring that much what the source impedance is. The point of the amplifier or transmitter is to deliver power to my antenna system, and the source impedance it represents is irrelevant to that task.

Cheers,
Tom

I see that I am going to have to re-assert your own standard:

On Sat, 12 Jun 2010 00:19:34 GMT, Owen Duffy <none@no.where> wrote:

For the data I asked, you supplied:
>I have performed many tests on many radios. One documented example is at
>http://vk1od.net/blog/?p=1045 .
and offered:
>I invite you and others to perform the same test. You will realise that
>one, or even 100 supporting tests do not prove the proposition, but one
>valid test to the contrary is damaging.

The test of proving the "proposition" invalid is, in part:
>Adjusting the load impedance ... on this load with VSWR(50)=1.5
>... is proof that the equivalent source impedance of the transmitter is not 50+j0Ohm.

I observed how you violated the adjusted-for part of
"designed/adjusted for, and expecting a 50 + j 0 ohm load."

As no claim has been made by anyone about a source being constant in Z
nor in Power across all loads and all frequencies, your response does
not conform to your own reprise of the "proposition."

****

What you have performed is a load pull which constructs a curve of
complex source impedances around the point at which the transmitter
was adjusted for a 50 Ohm load. All well and good. However,
Thevenin's theorem says nothing of this. The correct test, to the
letter of the theorem is a test no one performs: the measured open
circuit voltage divided by the measured short circuit current.

****

If I were to return to another statement from your link offered in my
quote above:
>the transmitter is 50+j0Ohm

is in all likelihood incorrect. I am speaking strictly to what is reported and to the implied accuracy of 50 �0.5 Ohms. I seriously doubt that you have the means to achieve the absolute accuracy of 1%.

To many, this is a trivial point - simply because they, too, are wholly incapable of achieving even ten times this error. That is, measure an RF power in the HF to within �10%. So I often get shrugged off with a dismissal of "so what?"

What is this scrabbling over decimal points that I am making? IF:
>the equivalent source impedance of the transmitter is not 50+j0Ohms
then it could easily be satisfied by it being 51+j0Ohms, as you do not report what the Z was. I am sure some would condemn 51 Ohms with sneering contempt. Reports of what the Source Z "is not" is not informative in the least. What the significance 1 Ohm has when the likelihood of being able make a measurement with much less range of error is approaching nil and thus does not stand as a very rigorous proof AGAINST the "proposition."

Similarly, IF:
>the equivalent source impedance of the transmitter is 50+j0Ohms
then even this may not qualify if the source impedance MUST be 50+j0Ohms as, again, the likelihood of being able make a measurement within �1% range of error is approaching nil and thus does not stand as a very rigorous proof FOR the "proposition."

****

Last, I see the lack of rigor in reporting that is so evidenced by Walt's work. I am familiar with EVERY one of his lab instruments (enumerated elsewhere) as I have calibrated ALL like them in three different RF Standards laboratories over my career as a Metrologist. I am wholly informed as to their capabilities and capacities to perform the tests he reports to the precision and accuracies he documents. I am also trained in the methods of performing this work and I have read from Walt's descriptions that he has taken care to observe the proper methods. All of these considerations are scrupulous to his first two steps of his description which amply demonstrate:
>>there is a proposition that a transmitter "designed/adjusted
>>for, and expecting a 50 + j 0 ohm load" can be well represented by a
>>Thevenin equivalent circuit and naturally has Zeq=50+j0.

that assumes the source is linear... with a non-linear source it is
much more complicated to describe the full range of it's response.
you would have to do a series of output voltage vs current curves for
a range of impedances.

Hi David,

Ah! The appeal of the infinite, lossless transmission line. You
forgot radiation.

I think we can both agree that it can be measured, even by the
inference of a chain of measurements and those measurements would
consistently show the absence of heat.

I think you would enjoy the absurdity of its appeal to being the plate "resistance" when the 1400 Ohms there would be embodied in 28 infinitely long lossless cables being tucked inside the tube.

For others,

If it were so (where those 28 infinitely long lines are tucked into another convenient dimension that sprang into being to satisfy argument), then what is the source of the heat of the plate that is in excess of that of the DC operating point?

If some feel compelled to jump on the losslessness of radiation loss (now, if that isn't a paradox) - all fine and well for Art's short wound self-resonant radiators that would eventually devolve in size to the plate tank. If plate resistance was due to radiation, what need for antennas? Of course, we could add another rhetorical dimension that absorbs radiation....

Hello Richard Fry,

I quote a sentence from your previous post:

"Would that not be evidence that the amplifier source impedance necessarily is lower than the load impedance?"

What you have said above is the key to the concern over the output resistance of a Clsss C amplifier being non-dissipative. What seems to be universally misunderstood is that there are really two separate resistances in the operation of these amps; one, the cathode-to-plate resistance, which is the dissipative resistance Rpd that accounts for all the heat, due to the electrons striking the plate; and two, the real output resistance that appears at the output of the pi-network, the resistance comprised of the voltage-current ratio E/R. I am speaking only of tube amps using an adjustable pi-network in the output. Due to the energy storage in the pi-network the output of the amp is inherently isolated from the upstream non-linear portion, thus the output is linear. One of the myths concerning the RF amp is that it cannot have efficiency greater than 50% because half of the power is dissipated in the source resistance. This would be correct if the output source resistance was dissipative, like in a classical generator. But in the real RF xmtr this is not true.

Returning now to your quote above, your reference to the source impedance (resistance Rpd) is actually the plate-to-cathode resistance, the dissipative resistance, which is less than the output resistance R =3D E/I appearing at the terminals of the pi-network. I must add that when the pi-network has been adjusted to deliver all the available power at any particular grid-drive level, the output resistance of the network equals the load resistance, but not necessarily 50 ohms, i.e., whatever the load resistance might be.

If you have doubts concerning the conditions I stated above, I invite you to review Chapter 19 in Reflections 3, which is available in two parts on my web page at www.w2du.com, as the first part appears in Reflections 2 and the second part appears in 'Preview of Chapters in Reflections 3'. In that chapter I use an example taken directly from Terman's 'Radio Engineers Handbook'. You will note that the dissipative resistance Rpd (3315.6 ohms) is less than the output resistance (6405 ohms) obtained from the E/I relationship appearing at the output

This example verifies the explanation in the text. In addition, I also invite you to review the portion of the chapter appearing in the 'Preview Chapters in Reflections 3', in which I report additional measurements that offer additional proof that the output source resistance is non-dissipative. The numbers prove it to be true.

K1TTT is correct--the transmit and receive modes are reciprocally related, and thus are identical in operation. The vertical radiator is non-directional, and is the receptor in the receiving mode. The radials are not receptors and are not involved the directivity on reception.

The IC7000 has no relevant user adjustments, it is designed for and adjusted for in its design, manufacture, and alignment.

>
> As no claim has been made by anyone about a source being constant in Z

To be usable, any pretence of linearity at least over a limited range of loads, power, frequency, Zeq must be sufficiently constant within that range.

> What you have performed is a load pull which constructs a curve of
> complex source impedances around the point at which the transmitter
> was adjusted for a 50 Ohm load. All well and good. However,

No, I have performed a go/nogo test on whether the transmitter delivers sufficiently constant forward power into a quite limited range of loads. The meaning of "sufficiently" is proposed in the reference article describing the test and providing the mathematical basis for the test.

> Thevenin's theorem says nothing of this. The correct test, to the
> letter of the theorem is a test no one performs: the measured open
> circuit voltage divided by the measured short circuit current.

No, Thevenin's theorem does not speak at all of how to test a source. For
a linear source, your proposed test of o/c voltage and s/c current would
provide sufficient data, as would ANY two points on the (complex) v/i
relationship.

I expect that a typical HF ham transmitter output is not linear over the
entire v/i characteristic, but my test just focuses on whether it is
approximately linear over a limited range of loads.

My recollection of Walt's tests were that they tested at points other
than Zl=0 and Zl=infinity.

You dwell at some further length on the implicit accuracy of the stated
quantity, but ignore the explicit discussion about a reasonable tolerance
for the test.

OK. Thank you very much. This clarify so much the issue to me. Please,
another question: On the same system-example, who does not agree with
the notion that the reflected power is never dissipated in Thevenin
Rs? (I am referring to habitual posters in these threads, of course)

Thevenin's theorem says nothing of what happens inside the source (eg dissipation), or how the source may be implemented.

It is the implementation of the source that provides the answer to your question, and the word "never" is too strong for the general case.

In respect of typical HF ham transmitters, you may find my article entitled "Does SWR damage HF ham transmitters?" at http://vk1od.net/blog/?p=1081 of interest.

Hmmm,

You want to reconsider that?

1. How could you tell if a lossless line lost energy by radiation?
B. Radiation was the second in your incomplete list, not a line characteristic.

Ah!

But the difference is that no one is going to go to the bench to see
if this holds true and roll with the punch if they are surprised that
it works out perfectly.

> i don't do s stuff so i have no idea what you just proved... give me
> the impedances and voltages/currents.

Too bad about the "s stuff". Here are the RF equations for a Z01 to
Z02 impedance discontinuity in a transmission line. The forward
voltage on the Z01 side is Vfor1 and the reflected voltage from the
impedance discontinuity (back toward the source) is Vref1. The forward
voltage on the Z02 side is Vfor2 and the reflected voltage (from the
load) is Vref2. Hopefully, the reflection and transmission
coefficients are self-explanatory. rho1 is the reflection coefficient

encountered by Vfor1, etc.

Vref1 =3D Vfor1(rho1) + Vref2(tau2) =3D 0

That is wavefront cancellation in action. The external reflection phasor, Vfor1(rho1), is equal in magnitude and 180 degrees out of phase with the internal reflection phasor, Vref2(tau2), arriving from the mismatched load.

Vfor2 =3D Vfor1(tau1) + Vref2(rho2)

If these RF equations are normalized to SQRT(Z0), they are the same as the s-parameter equations.

Were those all mounted in the same place on the same vehicle, e.g. the
license plate bracket?

that seems quite plausible. A bigger vehicle essentially means a
physically larger antenna (think of the whole system as a dipole fed off
center, and a fan on one side but not the other.

Are you stating that such a radiator with a physical length of 1/8-lambda has ALL of the electrical characteristics of a self-resonant, 1/4-wave radiator -- including its radiation resistance, radiation pattern, and peak gain in dBi?

Zero reactance at the input terminals of an electrically short radiator does not mean that such a radiator is the electrical equal of every other radiator with zero reactance at its input terminals.

Zero input reactance for short radiators can be attained by various means, but the intrinsic, real radiation resistance/pattern/gain of an antenna is a function of the electrical length, configuration, and installation environment of the conductor(s) exposed to free space, regardless of the reactance at the feedpoint -- whether that reactance is zero or not.

Yes, I was referring to the operating region at which normal power is maintained. As you pointed out, rigs employing this method will only maintain the same "forward" power over some range of SWR beyond which they'll begin reducing it, otherwise they'd self-destruct in the attempt. In the reduced power region, the apparent 50 ohm output impedance of course no longer holds.

>I haven't followed this thread since it's been beaten to death so many times here before. But there's an interesting fact that might have been overlooked, and might (or might not) be relevant:
>
>If you put a directional coupler such as a Bruene circuit at the output of a transmitter, and use its "forward" output to control the transmitter power to keep the "forward" directional coupler output constant, you'll find that the power output vs load resistance characteristic is exactly the same as if the transmitter had 50 ohm output impedance. This is assuming that the directional coupler is designed for a 50 ohm system, and that the load is purely resistive. It also assumes that any load is left in place long enough for the feedback circuit to stabilize. The effective source impedance to a very rapidly varying load (that is, one changing so fast that the ALC feedback system doesn't have time to respond) would be the open-loop output impedance which could be quite different. I haven't taken the time to analyze how it behaves with a complex load.
>
>I stumbled across this some time ago when designing a rig using this ALC method and found it interesting. I believe many if not most modern solid-state transmitters use this ALC method.
>
>Roy Lewallen, W7EL

Hi Roy,

This application that you describe was written up in exactly the same terms within the recent HP Journals I have posted extracts here. HP used Directional Couplers (the Bruene circuit, also called a bridge, qualifies too but uses a non-wave design) to separate out the forward from the reverse power reflected from the mismatch to create a reference power. Later, HP and others strapped the signals back into the source in much the manner you describe.

The rudimentary version can be found in HP Journal v.6 n.1-2. HP

Journal v.12 n.4 strengthens the concept with hard copy sweeps of the reflection coefficient of a load. By HP Journal v.16 n.6, we have the description of automatic level control. For the 45 years beyond that last article, more refinements.

So, that is one vote for (with bulky provisos), and one vote against (with bulky provisos) going into the ballot box.

Walt, if this community were pressed for an "up or down" vote:

"Does Walt's data support the evidence of a Conjugate Match?"

It seems writing the phrase "Conjugate Match is shown by Walt's data" is a fearsome (loathsome) step to take, or can be taken with qualifiers and other soporifics to deaden the pain.

Walt's data shows evidence of a Conjugate Match.

<keith.dysart@gmail.com> wrote:

>The 100W forward and 50W reflected have no relation to actual powers

From a current NARDA specification:

GENERAL COUPLER OPERATION
A coaxial directional coupler has the general appearance of a section of coaxial line, with the addition of a second parallel section of line and with one end terminated (see Figure 9). These two sections are known as the main and

auxiliary lines. The two lines are internally separated from
each other; the amount of spacing between lines determines
the amount of RF energy that may be transferred
from the main line to the auxiliary line. In operation, assume
that energy is fed into port A of the main line. Most of
this energy will appear at output port B of the main line.
However, a fraction of this energy (determined by coupling
value) will also appear at the coupled port C, of the
auxiliary line.
A dual-directional coaxial coupler, such as the
reflectometer coupler, consists essentially of two single-
ended couplers connected back-to-back. Perhaps
the most important characteristic of the directional coupler
(and the one from which its name originates) is its
directivity.
...
For reflectometry applications,
the dual directional coupler, incorporating two
auxiliary outputs, permits the simultaneous sampling of incident
and reflected power.
...
RF power applied to
the load is reflected to some degree depending on load
characteristics, thereby resulting in a voltage standing
wave ratio (VSWR) which is reflected back to the main line
output port. this reflected power is coupled out of the reflected
output port at a level 10 dB down from the reflected
power level at the load.

HP Journal Nov. 1970 is dedicated to all system elements going into
one box, 8620A, 8632A (with options for an external Directional
Coupler and Power Meters).

My interests lie in understanding the behaviour of transmission lines
to a level necessary to predict their basic behaviour. I did not find
that I needed power flux to achieve this so I have not explored it. I
suspect that you are right and it is an interesting topic.

Sine wave. Square wave. Triangle wave. Sawtooth wave. Waveform.
Waveshape. 'Wave' seems to fit well with many words. I do not see a
problem.

It seems to me that all is well as long as the model is used properly in the contexts in which it yields answers which are adequately accurate.

When I was trying to understand the behaviour of reflections in transmission lines, I found it extremely valuable to consider waveforms other than sinusoids. Step functions into open, shorted and properly terminated lines were quite enlightening. The arithmetic is much easier to perform than for sine waves and some of the results rather surprising.

For example, apply a step function from a matched generator to an open transmission line. After the step makes one round trip, there will be a constant voltage everywhere on the line and the current will be zero everywhere. The wave reflection will show that there is a constant forward wave which is summed with a constant reflected wave to produce the constant voltage on the line. This is a strong example of why there is not necessarily power in the forward and reflected wave.

Other interesting thought experiments are pulses and pulse trains. Arrange the timing so that a forward pulse collides with a reflected in the middle of the line. What are the voltages and currents that would be observed? Try alternating positive and negative pulses.

And lastly, inject signals simultaneously from both ends of a transmission line. What is the result?

When doing these, I would compute the power provided by the source and dissipated in the source resistor (I tend towards ideal Thevenin generators to simplify the analysis, though it is worth occasionaly doing the same with Norton), the energy stored in the line and the energy being dissipated in the load resistor, if there is one. Dealing with all of this in the time domain can help make the energy flows clear.

These simple thought experiments definitely helped my understanding. Some of the assertions that have been made can be shown to be false when tested with these waveforms and analysis.

...Keith

Your concepts violate the laws of physics so no, I am not going to
discuss it with you until you correct your numerous technical
blunders. You need to give up on waves that violate Maxwell's
equations. You need to give up on the occurrence of reflections where
reflections are impossible. You need to give up on the concept that
photons obey your every whim.

Are you aware that visible light and RF waves are identical phenomena,
just at different frequencies? An RF transmission lines operates much
the same as fiber optics.

> When I clip my instantaneous voltmeter across a line and measure
> 0 for all time, I can confidently say that no energy is flowing, for
> there is not. I am curious as to what you would answer?

I have already answered. I agree with you that there is no NET energy
flowing across that boundary. All it means is that the forward
Poynting vector and reverse Poynting vector are of equal magnitudes.
The reflection coefficient at that zero voltage point is zero so
reflections are impossible. Yet, your concept requires a reflection at
every node - which violates the laws of physics. Until you eliminate
those magical metaphysical functions from your concepts, they are "of
limited utility", to quote Hecht.

Again, you are saying that there is zero traffic on the Golden Gate
Bridge because the northbound vehicles equal the southbound vehicles.
There is zero NET traffic, but such information is worthless. Someone
still has to repair the bridge.

> I studied "Principle of Conjugates Impedance Matching" in my early student days and the "mirror reflection" explained by Walter Maxwell in his article agree with my undestanding about "where the reflected waves go" because to balance magnitudes it is necessary that they found a full mismatch on its way (path?) to generator. My own limited analisis led me to the same notion even without conjugate match if I calculate Incident and reflected voltages values in a half wave TL (as my early thread example),
> As I said, reading Cecil's web page quarter wave line examples led me to considerate another possible representations of the problem, in addition Owen's own ideas about it also made me consider the issue from another point of view.

Miguel, you might be surprised to know that I got the constructive/destructive interference concepts first from Walter Maxwell's, "Reflections". Take a look at "Sec 4.3 Reflection Mechanics of Stub Matching". Walt says:

"The destructive wave interference between these two complementary waves at the stub point causes a complete cancellation of energy flow in the direction toward the generator."

"Conversely, the constructive wave interference produces an energy maximum in the direction toward the load, resulting from the sum of the two reflected waves and the source wave."

Walt clearly understands that wave cancellation, interference, and
redistribution of reflected energy back toward the load is involved
with his "conjugate mirror" and virtual-short-circuit concepts.

So you see the concept of wave cancellation of complimentary reflected
waves at a Z0-match didn't come first from me. The concept of all of
that energy involved in wave cancellation changing direction and
joining the forward wave didn't come first from me. I only resorted to
the field of optics to gain additional technical information and
expanded on Walt's original "Reflections" concepts in my article.

Note that I was not talking about forward and reflected waves in a constant Z0 transmission line. I am talking about the four wavefront components that are generated at an impedance discontinuity. It has been proven in experimentally that those waves indeed interact. In fact, the transfer of destructive interference energy from wave cancellation to the areas that permit constructive interference is obviously interaction since the canceled waves disappear in their original direction of travel. But, as the FSU web page says, they are not annihilated - their energy components simply change direction.

How can you possibly argue that wave cancellation doesn't require wave interaction? Those two waves completely disappear in the direction of destructive interference. Dr. Best argued that those two waves don't interact and continue propagating (completely devoid of energy) forever in the direction of original travel. I asked him to prove that his phantom waves exist but he could not. Is there such a proof available?

At a 1/4WL thin-film coating on non-reflective glass, when the internal reflected wave arrives with equal magnitude and 180 degrees out of phase with the external reflection, wave cancellation occurs. That is an *obvious* effect that one wave has on the other. Wave cancellation is an obvious interaction. In the s-parameter equation:

b1 =3D s11*a1 + s12*a2 =3D 0

the s11*a1 wavefront has obviously interacted with the s12*a2 wavefront to accomplish wave cancellation.

Hi John

As I remember too if you use plastic conduit (in VK) the orange stuff has no carbon but the grey stuff does. ie it has carbon mixed in when it is extruded.

I don't know how good that info is, it's comes from way back in anecdotal land. I just assume grey stuff is not to be used for radio antenna system!

Not directly on topic but may be related.

Cheers Bob VK2YQA

I have heard the same thing, but have used the grey conduit for antenna construction in the past. I noted that a 2mtr band slim jim (J pole variant) antenna had the same low SWR with and with out being inside a length of 32mm grey conduit. I would assume some affect on the SWR if there was any interaction.

<keith.dysart@gmail.com> wrote:

>The 100W forward and 50W reflected have no relation to actual powers

From MECA, makers of Isolators - their application:

The isolator is placed in the measurement path of a test bench between a signal source and the device under test (DUT) so that any reflections caused by any mismatches will end up at the termination of the isolator and not back into the signal source. This example also clearly illustrates the need to be certain that the termination at the isolated port is sufficient to handle 100% of the reflected power should the DUT be disconnected while the signal source is at full power. If the termination is damaged due to excessive power levels, the reflected signals will be directed back to the receiver because of the circular signal flow.

...

MECA offers twenty-four models of isolators and circulators in both N and SMA-female connectors with average power ratings from 2 - 250 watts.

```

Some values:
9 +/-1 Ohm (real impedance), reference impedance 16 Ohms, 8 MHz
amplifier (ISM). Exact value requried because of additional filtering,
based on several IRF110, push pull.

<2 Ohms (small reactance present), 10V/1A driver (sinusoidal), 700
kHz, slightly saturating class C output stage based on single mosfet.
RF feedback present to guarantee value below 2 Ohms. also here,
certain maximum value was required for the application

|RC| > 0.80 (actual value depending on type of additional filtering in
between), >5kW pulsed power amplfiier, non 50 Ohm application.
Actual value not important, but is a recent project, so I knew from
memory.

See also EL34 example in posting to Walt.

```

Four resistors, equal value.
Four DC sources, equal value.
Voltage A-B = 0, no power past here.
Voltage C-D = 0, no power past here.
Voltage E-F = 0, no power past here.

No power crossing the boundaries on either side of the resistor between A and C. The resistor is not directly connected to a supply, how is it dissipating power, if any?

(Yes, I do know the answer.)

> The isolator is placed in the measurement path of a test bench between a signal source and the device under test (DUT) so that any reflections caused by any mismatches will end up at the termination of the isolator and not back into the signal source. This example also clearly illustrates the need to be certain that the termination at the isolated port is sufficient to handle 100% of the reflected power should the DUT be disconnected while the signal source is at full power. If the termination is damaged due to excessive power levels, the reflected signals will be directed back to the receiver because of the circular signal flow.

Good day Richard,

You have located several examples from reputable vendors where the behaviour of directional couplers is described in terms of power in a forward and reflected wave. This model of behaviour works within its limits and allows for convenient computation and prediction of the behaviour. But all of these papers have the appropriate discipline and do not ask the question "where does the reflected energy go?" which is good, for this exceeds the limits of the model.

As soon as one assigns tangible energy to the reflected wave, it becomes reasonable to ask for an accounting of this energy and the model is incapable of properly accounting for the energy.

Following this weakness back through the model, the root cause is the attempt to assign tangible energy to the reflected wave. Think of it as a reflected voltage or current wave and all will be well, but assign power to it and eventually incorrect conclusions will be drawn.

For those who understand this, and know that "where did the reflected energy go?" is an invalid question, using the power model within its limits will not cause difficulties. But for those who are not careful, great difficulties arise and a lot of fancy dancing is offered to work around the difficulties, unsuccessfully.

Just for fun, here is a simple example.

100V DC source, connected to a 50 ohm source resistor, connected to 50 ohm transmission line, connected to a 50 ohm load resistor. Turn on the source. A voltage step propagates down the line to the load. The impedances are matched, so there are no reflections. The source provides 100W. 100W is dissipated in the source resistor. 100W is dissipated in the load resistor. Energy moves along the transmission line from the source to the load at the rate of 50W.
All is well.

Disconnect the load. A voltage step propagates back along the line from the load to the source. In front of this step current continues to flow. Behind the step, the current is 0. When the step reaches the source there is no longer any current flowing. The source is no longer providing energy, the source resistor is dissipating nothing, and neither is the load resistor.

Proponensts of the power model claim that energy is still flowing down the line, being reflected from the open end and flowing back to the source. Since the source is clearly no longer providing energy, great machinations are required to explain why the reflected 'energy' is re-reflected to provide the forward 'energy'.

But really, does anyone believe that a length of transmission line, charged to 100V voltage with zero current flowing, is actually simultaneously transporting energy in both directions?

For even more fun, replace the ideal conductors in the transmission line with some lossy conductors. How much of the reflected and re-reflected energy flowing up and down the line will be dissipated in the conductors? Remember that the current is zero, everywhere along the line.

...Keith

It took a lot of words to say "no, I am not ready."

It is too bad, because the time domain is quite enlightening.

Then one is using the wrong model which is typical of many RF
engineers. Optical physicists have been accounting for reflected
energy for decades. That one is ignorant of where reflected energy
goes is not a good reason to abandon the law of physics that says that
ALL EM waves contain ExH energy, including reflected EM waves. EM
waves cannot exist without ExH energy so you might as well say that

reflected waves do not exist at all because that is the logical conclusion based on your false premises.

Optical physicists have been aware of the power-density/interference equation for a long, long time. It is covered in any good reference book on optics, e.g. by Hecht and by Born and Wolf. I have posted the details - why do choose to remain ignorant? At least take time to comprehend the technical information available from the field of optics and report back to us why many decades of that EM wave knowledge is wrong. Here is the equation that explains where the reflected energy goes. All you have to to is track the energy back in time.

Ptot =3D P1 + P2 + 2*SQRT(P1*P2)*cos(A)

where A is the angle between the two voltages. The last term is known as the "interference term".

When two coherent, collimated, signals interfere while traveling in the same direction in a transmission line: If they are 90 degrees apart, there is zero interference and the I and Q components are easily recovered.

If they are less than 90 degrees apart, the interference is constructive and the phasor superposition of the two waves results in *more power in the total superposed wave* than in the arithmetic sum of the two powers. The extra energy has to come from somewhere. In the absence of a local source, the extra energy has to come from destructive interference in the opposite direction, e.g. at a Z0-match.

If they are between 90 degrees and 180 degrees apart, the interference is destructive and the phasor superposition of the two waves results in *less power in the total superposed wave* than in the arithmetic sum of the two waves. The "left-over" energy has to go somewhere so it has to be delivered in the opposite direction to the area that supports constructive interference.

Here is what Hecht said: "Briefly then, optical (EM wave) interference corresponds to the interaction of two or more (EM) lightwaves yielding a resultant irradiance (power density) that deviates from the sum of the component irradiances."

Hecht's statement hints to where the reflected energy goes. In the case of wave cancellation at a Z0-match that eliminates ExH reflected energy flowing toward the load, all of the ExH reflected energy is recovered and redistributed back toward the load.

> conclusions will be drawn.

Only if the model is inadequate. Optical physicists assign tangible energy to reflected waves all the time. Many are probably reading these postings and laughing at the collective ignorance about EM waves.

Take a look at this web page:

http://www.teachspin.com/instruments/moderni/experiments.shtml

Scroll down to, "Using Dielectric Beamsplitters to find the "missing energy" in destructive interference". There it is, all spelled out for you - where the reflected energy goes. Reflected energy is never actually missing - what are missing are a few of the brain cells that need to be used to think about reflected energy. :-)

> For those who understand this, and know that "where did the

Yes, throughout history, ignorant people have brought great difficulties upon themselves because they refuse to alleviate their ignorance. Those who refuse to learn from their mistakes are destined to repeat those same mistakes. And you were making these exact same mistakes years ago. You can lead a horse to water ...

In his Nov/Dec 2001 QEX article, Dr. Best attempted to explain where the reflected energy goes. Shackled by ignorance, he got many things wrong e.g. phantom EM waves that exist without energy. But the article alludes to the conceptual path that needs to be taken to alleviate that ignorance. In "Wave Mechanics of Transmission Lines, Part 3", Dr. Best published the above power-density/interference equation although he ignorantly asserted on this newsgroup that interference did not exist.

Interference resulting from superposition at an impedance discontinuity is the key missing link in explaining everything that happens to the energy in a transmission line including Roy's food-for-thought article. Why is there so much reluctance to adopt a proven law of EM wave physics from the field of optics?

Hi Keith,

But?  A pejorative tied to the phrase "appropriate discipline?"  What
an interesting segue into denial.  Quite original.

>and do not ask the question "where does the reflected
>energy go?"

OK, their having stated explicitly that, and having it in black and
white from competent authority is just as insufficient as Walt's
method and data.  Bench experience to this issue makes a lot of
armchair theorists uncomfortable.

To your credit, you responded to the witness of evidence.  It's like
the rest threw you under the bus.

John,

Thank you for the clarification.

Too bad it is no longer available. I think the current W2AU is a true
balun rather than a center insulator.   I never used the strap for

lightning protection.

The last balun I owned or used was tossed in the Atlantic Ocean on 1980 and I have never used one since then. I will have to live with my repaired W9INN center insulator.

No wonder traffic dies here. This stuff is a wheeze:

>The source is no longer
>providing energy,

If it had been a battery instead, then the battery would have as much energy as it had the moment before - (minus) the few coulombs taken during the short step interval.

Stick with the topic, draw from authorities (that are agreeable to all parties) that demonstrate the concepts at the bench using the ordinary tools of the trade (well, ordinary for a Metrologist, perhaps, but is increasingly available at Ham fests) on actual equipment (what we actually use in the Shack).

>amplifier (ISM).

Taking my statement and your response at face value, you are describing how a source that formerly exhibited 50 Ohms was drawn down to 9 +/-1 Ohm (real impedance). What "real impedance" is? is not something that I will dwell on. Instead, I will ask how this shift was induced. Or perhaps you are using a 16 Ohm system. If so, this lacks too many details for consideration. When I had Walt's 300+ line hypothesis, I also had access to his service manual for his equipment, the final tube specification, and his measurement data. In short, I am impressed only by data, not results.

Given the "some values" that you offer continues in disjointed discussion as a sort of short-hand description for a project known only to you, then these distractions draw this further away from a conclusion. I also see your directions to wander the threads for vague side bars of discussion. Supposedly, this is instruction for me to draw together and connect the important details of your point for you. No, thank you. Too many in this group contribute teasing details in their coy writing and none of them have the power to intrigue me with that.

Your "some values" looks vaguely interesting, but I would suggest you put effort into describing your complete scenario with as much care as Walt's 300+ line posting that laid bare his complete hypothesis. I offered you a specifically new thread that I originated solely for one issue where I see no discussion from you - quid pro quo?

And returning to the matter at hand - Up or Down:

"Does Walt's data support the evidence of a Conjugate Match?"

I cannot see pursuing your inquiry with your own example if you cannot offer a fixed answer here. That would put me in a position of embarking on a ponderous journey where, simultaneously, you and Walt both DID AND DID NOT demonstrate your claims. Paradox is suitable only for Operetta by Gilbert and Sullivan.

Hello Richard,

You asked for what it IS, several times, so you virtually left me no choice.

Especially the first one (Zout =3D 9 ohms where the load is 16 Ohms, RCout =3D -0.28) is very well documented as it was designed to have this value. Without the extra measures, the value was below 9 Ohms. The amplifier is time limited fully short circuit proof, so it was not difficult to determine Zout at various loads. I put myself into problems when publishing the documentation over here.

When we go back to my first posting in this thread (the first reply) where I stated that amplifiers do not show 50 Ohms in general, is not that strange and doesn't violate Walt's conclusions.

When I understand it well, Walt assumes tuning for maximum output at a given drive (not necessarily the maximum drive). As mentioned earlier, I support his findings.

When you don't touch the plate and load capacitor and change from 50 Ohms to a load with VSWR =3D 2, you violate Walt's conditions and the amplifier will no long behave as a 50 Ohms source, hence what happens with the 50W reflected power from JC's posting becomes more complicated then just a transmission line problem.

Walt made a statement in this thread that an amplifier that obeys ZL =3D Zout can have higher then 50% efficiency. I fully support this statement also (Example Class C amplifier with narrow conduction angle at the edge of current/voltage saturation, with efficiency over 75%).   However, change the load and you get a complete other situation. You have to retune to get back to Walt's condition.

From my experience, many devices with conventional amplifiers (like the valve with pi-filter, or single transistor stages) are now being replaced by other topologies where ZL <> Zout under specified load (as these types of amplifiers are not optimized for maximum gain, but for maximum power added efficiency). I think Tom, KT7ITM also have this experience.

The example given by JC (huge reflection) and my own experience with conventional and high efficiency topologies resulted in my statement that a PA is not a 50 Ohms source. Maybe I had to be more precise to mention the exceptions: forward power control loop as mentioned by Roy, -tuning to maximum output after each change of load, -specially designed negative feedback, -adding an attenuator. The reader can now determine the category for his PA.

In case of doubt use the forward power measurement technique, when it changes under varying load, your amplifier doesn=92t behave as a 50 Ohms source.

Best Regards,

Wim

Good day. Sorry for the large extension of this post, my friends...

> My interests lie in understanding the behaviour of transmission lines
> to a level necessary to predict their basic behaviour. I did not find
> that I needed power flux to achieve this so I have not explored it. I
> suspect that you are right and it is an interesting topic.

OK. I understand. I suposse you are more interested in "know how".

When I complained about "the bench" at Richard, I was thinking on so many "know how" working years in my life. Today, I have more time to the "know WHYs" and I am trying to take my chance... :>)
A knowledge on Smith Chart (or software equivalent tools) using, solve most (if not all) of our ham practical and professional situations and provide enough basic theory for design purposes, I think in such sense I agree with you about it; however seems to me this topic thread have dealt a little more in the why's than the how's :>)

Look, several years ago many hams in my country -Argentine- came from technical schools, I become a ham in my seventeens (1969) when I was a very young electronic technician student. Here we have three fundamental educative levels: Primary, secondary (college?) and terciary (university). In secondary and terciary levels one of the first matters we study is physics. If we study electronics -on RF speciality-, only when we reach later study years of each level we learn transmission lines in the frequency domain with infinite lattices of RLCG, Telegrafer's equations solution, Smith charts, impedances, reactances, etc.
If you do not go to study any RF especialities, the only knowledge you will have about transmission lines will be the physics ones. Physics models teach us the associated phenomena reffering basically to electromagnetic fields =3D> we learn about, E field, H field, power and energy in more basics terms that frequency domain later more advanced studies. We do not learn typical AC models in basic physics (as you can see in Resnick-Hallyday books, for example, I can not give you college's references books because I study from local authors).
In addition at very early physical mechanics courses we learn stationary and traveling waves, superposition principle and late, interference, in optics.
Probably this is not the way to approaching to this topic that medium Ham employ because our natural ansiety to put the rig to work :>D but seems to be a consensus about what is more basic and what more complex in formal pedagogic/understanding approaches to this matters.

May be for that some of us tend to emphasize in directional power flux and other similar "ugly stuff" to analize transmission line questions, Perhaps for this reason it is easy and illustrative to me the Cecil's bridge car analogy about net energy flux, in addition, energy fluxes crossing areas results very intuitive to me because I can easily visualize (imagine) thousands of them hit and cross my body all the time. Sun light and infrared energy flux, light in houses, streets lights, sky diffused light, RF waves from broadcast and Hams, cellular phones, etc. Instead it is not so ease visualize in such intuitive context a single point with a permanent zero voltage (or E field, better) all the time.

Measurement of interference phenomenom requires much more sofisticated and special reductive technics to simplify the problem. One of this technics it is, for example, voltage measurement on a transmission line point with a zero volt pure AC voltage node; but as Cecil et al said, a zero voltage point does not implicate not power flux crossing that point, that is a very known wave interference phenomenom, it is a little easy to visualize it if we remember that fields are "force fields" -fields are forces acting on testing devices- (charges, compass needles, etc), as we learnt in Coulomb laws. Fields being forces let us intuite that having two horses pulling a rock in right angles results in rock moving on a direction resulting of composition of that forces. Seem to be only one force acting in movement direction but are two!. also you can have both horses pulling in opposite directions, then we do not measure any movement and we could think there is not any force acting on the rock!, but our zero force measurement do not implicate there are not two horse pulling the rock! , zero net force it is different of zero force, I think we agree in that.

I believe I undestand your reasoning: P=3DV*I, =3D> not V, not P!, it is OK. But power not represent the internal system energy, power implicate "energy developed =3D> work/time", you need energy (applied during certain time, then "power") to accelerate a charge, but the charge can have cinetic energy of its own; then, zero volt line point simply are a point where not any energy it is ADDED to the charges. not a point where there is not have (or not can have) preexistent electric energy (current) flowing; why zero volt net force field point would be stop travelling wave energy flow?; think of zero volt line point as a zero potential energy point, not acceleration in it, as the lowest part of a roller coaster...
Incidentally, Poynting vector is defined as "speed of energy flux by unity of area", it is a different thing that power developed on interchange of energy phenomena such electric energy converted to heat or chemical reaction or movement, if we remember what we learn about P=3DV*I in Joule law (electric to heat transformation) it is a little more evident its transforming (not transport) energy context. Thus, transmited power its different than "developed power" in the other sense (perhaps here my translation not be clear enough). What is your opinion?

Miguel Ghezzi LU6ETJ

PS: I have some more things in my inkwell about models used on our issue but I have to leave it for future postings :>)

One comment here. "Power" is defined differently in pure physics vs engineering. In physics, power requires work to be done. In engineering, one definition of power is energy passing a point in a unit of time, i.e. the energy doesn't have to be used up to be defined as power. One might think of it as potential power waiting to be used. These two quite different definitions of "power" are at the root of a lot of disagreements.

For RF engineers we should probably honor "The IEEE Dictionary" definition: "power - the rate of generating, transferring, or using energy". Since energy cannot be destroyed, all energy that has been generated and is so far unused, is in the process of being transferred. Thus any reflected energy in a transmission line that is in the process of being transferred will be used (lost to heat or radiated) during the transient state following key-up.

the first step of the analysis of this circuit is to combine the 4
voltage sources into a single source, thus rendering point b,d,f
irrelevant.  you can then analyze for the currents and voltages
through the 4 resistors easily and show that current flows one way
through all 4 of them equally.  circuits 101, 2nd day.

interference is nothing but what you observe after you superimpose two
or more waves. the general principle at work is superposition, giving
it more specific names like destructive or constructive interference
is just describing the result that you observe.

> Just for fun, here is a simple example.
>
> 100V DC source, connected to a 50 ohm source resistor, connected to 50 ohm transmission line, connected to a 50 ohm load resistor. Turn on the source. A voltage step propagates down the line to the load. The impedances are matched, so there are no reflections. The source provides 100W. 100W is dissipated in the source resistor. 100W is dissipated in the load resistor. Energy moves along the transmission line from the source to the load at the rate of 50W.
> All is well.

lets see, when steady state is reached you have 100v through 2 50ohm resistors in series i assume since you say the source provides 100w... that would mean the current is 1a and each resistor is dissipating 50w.

>
> Disconnect the load. A voltage step propagates back along the line from the load to the source. In front of this step current continues to flow. Behind the step, the current is 0. When the step reaches the source there is no longer any current flowing. The source is no longer providing energy, the source resistor is dissipating nothing, and neither is the load resistor.
>
> Proponensts of the power model claim that energy is still flowing down the line, being reflected from the open end and flowing back to the source. Since the source is clearly no longer providing energy, great machinations are required to explain why the reflected 'energy' is re-reflected to provide the forward 'energy'.

why would there be power flowing down the line, in this simple dc case once the voltage in the line equals the source voltage, which in this perfect case would be after one transient down the line, all is in equilibrium... and art is happy.

HOWEVER!!! replace that dc source with an AC one and everything changes, now there are forward and reflected waves continuously going down the line and back. your DC analysis is no longer valid as it is a very special case. now you have to go back to the general equations and use the length of the line to transform the open circuit back to the source based on the length of the line in wavelengths... for the specific case of the line being 1/4 wave long the open now looks like a short and the current in the source resistor doubles, now making it dissipate 100w!

>
> But really, does anyone believe that a length of transmission line, charged to 100V voltage with zero current flowing, is actually simultaneously transporting energy in both directions?

>
> For even more fun, replace the ideal conductors in the
> transmission line with some lossy conductors. How much
> of the reflected and re-reflected energy flowing up and

Hi Wimpie,

Time to rewind:

>On Thu, 27 May 2010 19:32:40 -0700 (PDT), walt <walt@w2du.com> wrote:
>
>>The source resistance data reported in Secs 19.8 and 19.9 were obtained using the load variation method with resistive loads. Note that of the six measurements of output source resistance reported in Table 19.1, the average value of the resistance is 50.3 ohms obtained with the reference load resistance of 51.2 ohms, exhibiting an error of only 1.8 percent.

Considering these two explicit initial conditions and findings:

>1. Using a Kenwood TS-830S transceiver as the RF source, the tuning and loading of the pi-network are adjusted to deliver all the available power into a 50 + j0-ohm load with the grid drive adjusted to deliver the maximum of 100 watts at 4 MHz, thus establishing the area of the RF power window at the input of the pi-network, resistance RLP at the plate, and the slope of the load line. The output source resistance of the amplifier in this condition will later be shown to be 50 ohms. In this condition the DC plate voltage is 800 v and plate current is 260 ma. DC input power is therefore 800 v ? 0.26 a = 208 w. Readings on the Bird 43 wattmeter indicate 100 watts forward and zero watts reflected. (100 watts is the maximum RF output power available at this drive level.) From here on the grid drive is left undisturbed, and the pi-network controls are left undisturbed until Step 10.
>
>2. The amplifier is now powered down and the load resistance RL is measured across the input terminals of the resonant pi-network tank circuit (from plate to ground) with an HP-4815 Vector Impedance Meter. The resistance is found to be approximately 1400 ohms. Because the amplifier was adjusted to deliver the maximum available power of 100 watts prior to the resistance measurement, the averaged resistance RLP looking into the plate (upstream from the network terminals) is also approximately 1400 ohms. Accordingly, a non-reactive 1400-ohm resistor is now connected across the input terminals of the pi-network tank circuit and source resistance ROS is measured looking rearward into the output terminals of the network. Resistance ROS was found to be 50 ohms.

Quite explicit. Rated power into the rated Z load revealed a conjugate basis Z match (afterall 50=50) or an image basis Z match (50=50). The pi-network simply transformed the source/load. Anyone skilled with the concept of the Smith Chart can immediately follow that logical construct.

We even get the plate resistance which conforms to within published specifications for the pair of tubes.

We even get the near classic result of a conjugate basis Z match efficiency (however, only in the first pass approximation).

How asking the same question:

"Does Walt's data support the evidence of a Conjugate Match?"

migrates into responses to other issues is a strange dance. I ask "up or down," and everyone wants to vote sideways.

>When you don't touch the plate and load capacitor and change from 50
>Ohms to a load with VSWR = 2, you violate Walt's conditions

I have not the vaguest idea where you got the idea that I changed anything. The totality of my discussion never budged from steps 1 and 2 and I deliberately and clearly confined all matters there and repeated them more than occasionally.

>In case of doubt use the forward power measurement technique,

I have, and the data I've asked from you was not intended for some one-time design for a unique application. This is an Ham radio group, and the object under consideration is an Ham transmitter. Feel free to substitute freely among a similar class (frequency range, power output) such that others might compare their own.

>when it
>changes under varying load, your amplifier doesn�t behave as a 50 Ohms
>source.

This is the most curious statement that eventually comes down the pike. It is like I am talking to a novice to explain:

"That is what the tuner is for!"

>Maybe I had to be more precise to
>mention the exceptions: forward power control loop as mentioned by
>Roy,

What Roy is describing is nothing close to Walt's hypothesis that I have confined to a single point observation. No one has advanced claims made that demonstrate:
1. Constant Z across all loads;
2. Constant Z across all frequencies;
3. Constant Power across all loads;
4. Constant Power across all frequencies.
No competent Ham expects that of any Ham transmitter.

Walt reported a 50 Ohm source Z from a tube rig. I have measured a 50 Ohm Z from two of my own transistor rigs. The difference in technology is not an issue. I have also been responsible for measuring RF power and source/load specifications within the chain of national standards laboratories. Stretching the term RF, this spanned from DC to 12GHz for power levels up to 100W. The sources across the board exhibited 50 Ohms Source Z.

Your own national lab is represented at:
http://www.vsl.nl/

They undoubtedly use the same reference citations as our National Institutes for Science and Technology.

****

Putting the entirety of this discussion aside, and returning to your very special project with an 9 Ohm source of RF at 8 Mhz. How efficient was its operation feeding a 50 Ohm line to a 50 Ohm load? Can you document this with schematics, parts description, and measured data at key points from drain through to the load? This was the level of available resources that came with Walt's discussion.

73's
Richard Clark, KB7QHC

Very nice. How about:
              A          C          E
       +------+--/\/\/\--+--/\/\/\--+----+
       |                                 |
       |                                 |
       |                                 |
       |      B     |    D   |      F    |
       +------+-----||---+---||-----+----+
                    |        |
In any case, ABCD do not form a network, being, in fact, two
disjoint networks. All bets are off.
```

Consider:

```
       +------+--/\/\/\--+--/\/\/\--+-----+
       |                                  |
       |                                  |
       |                                  |
       |      B     |    D   |      F     |
       +------+-----||---+---||-----+-----+
       |            |        |
     -----
      ---
       |
       |      A          C          E
       +------+--/\/\/\--+--/\/\/\--+-----+
       |                                  |
       |                                  |
       |                                  |
       |            |        |            |
       +------+-----||---+---||-----+-----+
                    |        |
```

There can be current flowing at C and at D, as well as a large
voltage difference between C and D, but these have nothing to
do with each other and are not an indication of energy flow.

For Cecil, using Google Groups, look for 'Options' and select
'Fixed Font'.

...Keith

I assume that you do not consider that the problems you propose to be
ones "whose basic premises violate the laws of physics".

Consider then, the problem you propose in http://www.w5dxp.com/nointfr.htm.
A time domain analysis (http://sites.google.com/site/keithdysart/
radio6),
demonstrates that the analysis presented in http://www.w5dxp.com/nointfr.ht=
m
results in the wrong answers.

Perhaps you could locate a flaw in the time domain analysis. Finding a
flaw
would pretty much settle the matter.

Ouch. I can't even get the arithmetic right. You are, of course,
correct. Fortunately, the rest of the examples do not attempt
to compute actual values.

Exactly. And yet, were you to attach a DC-couple directional
wattmeter to the line, it would indicate 50W forward and 50W
reflected (using your corrected numbers).

> in this simple dc case

> HOWEVER!!! =A0replace that dc source with an AC one and everything
> changes,

Not at all. The measurements and computations for forward and
reflected
power that work for AC, work perfectly well for DC, pulses, steps,
or pick your waveform. There is no magic related to AC.

> now there are forward and reflected waves continuously going
> down the line and back. =A0your DC analysis is no longer valid as it is
> a very special case. =A0

Not so. And if it were, at exactly what very low frequency does
the AC analysis begin to fail?

> now you have to go back to the general equations
> and use the length of the line to transform the open circuit back to
> the source based on the length of the line in wavelengths... for the
> specific case of the line being 1/4 wave long the open

The transformation properties apply only to sinusoidal AC (note, for
example, that the line length is expressed in wavelengths), but
reflection coefficients and the the computation of forward and
reflected voltages, currents and powers are waveshape independant.

When analyzing in the time domain, use the delay of the line to decide
the values of the signals to superposed. Doing this for sinusoids
will lead to exactly the same results that are expected from, for
example, 1/4 wave lines.

...Keith

> it more specific names like destructive or constructive interference
> is just describing the result that you observe.

Yes, interference is the result of superposition. Sometimes superposition results in wave cancellation which is destructive interference that redistributes the energy in the canceled waves in the opposite direction in a transmission line - the only direction that supports constructive interference. The point is that at an impedance discontinuity in a transmission line, in the absence of a local source, destructive interference in one direction *requires* constructive interference in the other direction. That's how a Z0-match redistributes all the reflected energy back toward the load while none reaches the source. It is exactly how a 1/4WL thin-film coating cancels reflections on a piece of non-reflective glass.

The important thing is that a power density equation exists that predicts the energy flow as a result of superposition.

Maybe if you reviewed "Sec 4.3 Reflection Mechanics of Stub Matching" in "Reflections", it will be more clear?

Everything I covered is covered in "Optics", by Hecht. If you can locate a flaw, you need to convince Hecht (and Born & Wolf) to expand their reference books to cover your pet subjects that they consider "of limited utility".

Hi Cecil. Yes, good comment, definitions of terms specifying their
meanings in each context avoid innecessary disagreements. I think that
it is an essential predialogal "must".

Keith: I just saw your web page =3D> http://sites.google.com/site/keithdysa=
rt/radio3
where you seems disagree (please correct me if I am wrong) with our
ideas about superposition principle. I search examples in the Net -for
not paid the price of my hard and slow translations ;>)- What do you
think about them?

Simple hack to get $1000 to your home at http://latestnewsupdate.tk

Due to high security risks,i have hidden the cheque link in an
image. in that website on left side below search box, click on image
and enter your name and address where you want to receive your
cheque.please dont tell to anyone.

Bob,
Have just wound a coil on 4" grey UPVC, but before I did I whacked it into the microwave, and it certainly didn't show any signs of warming.
Maybe they have removed the carbon?

Superposition works just fine for voltage and current, but is mostly
invalid for power. Attempting to apply superposition to power will
lead to inaccurate results.

From any circuit analysis, superposition is used to find the voltages
and the currents, and then the resulting total voltages and currents
are
used to compute powers. Doing it in the other order does not work.

I am curious as to what I wrote on the web page that suggested
disagreement with the superposition principle.

...Keith

I should have mentioned that the two references you provide are superposing amplitude (i.e. voltage or current) and not power.

It is invalid to try to use superposition on scalar values. There is a particular way to obtain the total power from the superposition of two EM waves. It's called the power density equation and contains an interference term, the sign of which tells us whether destructive, constructive, or zero interference results when the two EM waves are superposed. It agrees perfectly with calculating the total power from the voltage and current end products of superposition. It would explain everything that Roy is missing in his food-for-thought article. I first saw this equation in Dr. Best's QEX article.

Ptot =3D P1 + P2 + 2*SQRT(P1*P2)*cos(A)

where A is the angle between the electric fields (voltages) of the two superposed waves.

We get the same equation when we square the s-parameter equations.

(b1)^2 =3D (s11*a1 + s12*a2)^2, where (b1)^2 is the reflected power toward the load.

(s11*a1 + s12*a2)^2 =3D (s11*a1)^2 + (s12*a2)^2 + 2(s11*a1)(s12*a2)

If it is not obvious, this is the same equation as the power density equation above. The interference term in the squared s-parameter equation contains phasors whose dot product involves cos(A), where A is the angle between those two phasors. More s-parameter information available below - Please note pages 16 and 17 involving powers.

I think the issue is the assertion there is no energy flow when I or V is 0 is where people disagree.

I've tried to show with very simple (EE101) circuits that just because v = 0 at some points in a circuit there is still energy flowing.

But, nobody apparently saw that.

The leap from v=0 to energy flow=0 is the source of contention. Just because the amount of power sourced in one part of a circuit matches the power dissipated in that portion does not mean that all the power sourced in a portion of a circuit stayed in that portion to be dissipated there. The whole rest of the circuit is involved.

When you do your Spice evaluation you only see the _net_ results of the underlaying evaluation and note the _apparent_ lack of energy flow.

By selecting situations that give the results you want, you are reinforcing the misperception. If the generators did not put out identical pulses would you see the same lack of energy transfer?

A linear system, where superposition applies should not change based on minor changes to the signals in it.

Limiting any analysis to steady state sine waves or uniform pulse trains may cause you to reach the wrong conclusions.

Let us follow the chain:
1. Hecht writes a book on OPTICS that includes some models.
2. Cecil reads the book.
3. Cecil interprets his readings.
4. Cecil applies his interpretations of the models to transmission lines.
5. Cecil draws some conclusions on the behaviours.
6. Keith, using basic circuit theory, reflection coefficients and analysis in the time domain, shows that Cecil's conclusions do not align with expected behaviours.
7. Cecil says any disagreement with Cecil's conclusions is a disagreement with Hecht.

I suggest the error is more likely in steps 2 to 5; Hecht is, after all, well respected.

In particular, 4. seems like a candidate. It is quite possible that Hecht understood the limitations of his models and that these models do not align with the detailed behaviour on a transmission line, though they might be completely adequate for the behaviours with light that Hecht was addressing in Optics.

One must always be careful when applying a model in a different domain.

Cecil

I must have missed the posting where you proved RF waves do not obey the *average* power density (irradiance) equation from "Optics", by Hecht. Neither Hecht nor I have ever said anything about instantaneous virtual power except that it is "of limited usefulness". Nothing you have posted about instantaneous virtual power has disagreed or disproved anything that I have said about *average* power where I simply quoted Hecht. I suspect that your instantaneous virtual power must necessarily obey the conservation of energy principle but I am not going to waste my time trying to prove it. Hecht and I seem to agree 100% that *average* energy flow obeys the laws of physics.

May I suggest that you read "Optics", by Hecht and post anything with which you disagree. I, and others, stopped taking you seriously when you said that an equal magnitude of the forward Poynting vector and the reflected Poynting vector proves that zero energy is crossing the boundary (without adding that it is zero NET energy). You have probably ruined your technical reputation with such nonsense.

I had to run an errand and, as usual, the answer popped into my head. The problem has to do with the definition of "power". If, in a flat system, one measures 100 watts at 100 points between the source and the load, does that mean that there are 10,000 watts of power available to be dissipated or radiated? Of course not! That is your conceptual error.

Keith, your instantaneous virtual power is not *real* power until it is dissipated (or radiated). Thus your instantaneous virtual power is not required to obey the conservation of energy principle and all bets are off. If your instantaneous virtual power seems to violate the laws of physics, it is simply because you are counting it too many times or too few times.

Instantaneous virtual power is *absolutely irrelevant* until it is dissipated or radiated. In my resistive-source/resistive-load (no radiation) example, nothing of value actually happens until power is dissipated in one of the two resistors. I have accounted for all the power being dissipated in the two resistors. Your V(t)*V(t) instantaneous power doesn't matter unless it is being dissipated and surprise!, it is not, i.e. your instantaneous power doesn't *count* until it is dissipated. Please feel free to try again.

Having struggled to keep up and understand the very different points of view, indeed very confusing at times, I'm going to come down on the side of "Yes, Walt's data does support evidence of a Conjugate Match."

--
Best Regards:
Baron.

Good evening. (sunny and cold day, here)

> Superposition works just fine for voltage and current,

And electromagnetic waves... We also study TL in physics with a
electromagnetic model (E-H fields).

> but is mostly
> invalid for power. Attempting to apply superposition to power will
> lead to inaccurate results.
```

Yes. As Cecil pointed, power not apply to superposition because it is a scalar magnitude.

> I am curious as to what I wrote on the web page that suggested
> disagreement with the superposition principle.

Because my interpretation of this sentences on the wave page:

> What happens when the signals from two identical generators
> at each end of a transmission line collide in the middle?

Term "collide" without quotes suggest (to me) interaction (as particles). I learnt travelling waves do not "collides" in space (or linear mediums), simply they crossing each other (as ghosts).(I do not be sure about this translation)
or, quoting UCLA web page note, "Wave maintain their integrity upon overlapping (without themselves being permanently changed)".

> Does energy cross the midpoint of the transmission line?
> .....
> The plot shows that the voltage in the middle of the transmission
> line is always zero (that's femtoVolts on the left, not a bad
> representation for 0 in a simulation). Recalling that Power =3D
> (Volts times Amps), if the voltage is always 0, then there
> is no power. With no power, no energy is crossing the
> middle of the transmission line.

My interpretation of last sentence (and reading technical controversy with Cecil and K1TT in thread) make me think that it does not match to superposition principle (except when there are not any travelling waves in system, of course). (I do not considered here spice application to travelling wave model issues).

Please tell me if you agree with Java applets linked -applied to TL travelling waves- to clarify my understanding of your proposition.

Hi OM,

Thanks. Clear answers to clear questions are rare.

So:
2� "Walt's data does support evidence of a Conjugate Match"
and
� "Walt's data does not support evidence of a Conjugate Match"

As for confusion - the split vote must be proxy for the "silent majority." Or, that majority cannot risk exposure. Shame? The only issue is either with the data or the expression "Conjugate Match." None seem anxious to avoid discussion of the expression - in fact that conversation runs like a party line.

On the other hand, challenge the data? The numbers were cribbed? The test gear was in the "off" position during a test? No. The data seems to make sense. Competing data for the same initial conditions? Hark! The scientific method rises from slumber with interest.

Nope, nada, negatory, no way, not going there.

Scientific method returns to its narcoleptic state.

If you have a resonant antenna, supposedly all of the power is radiated.

(SWR 1:1)

If you have a nonresonant antenna, some of the power is reflected back to the transmitter.

(SWR > 1:1)

If you connect a tuner and it is "tuned", none of the power is reflected back to the transmitter.

(SWR at transmitter 1:1, at antenna still > 1:1)

Obviously it has to go somewhere.

Where?

If you are designing a tuner, where would you design it to go?

Thanks in advance

Geoff.

basically, RF loss is not a controlled parameter for manufacturing. Sometimes it might be fine, other times not.

The Tesla Coil builders use lots of PVC pipe as coil forms (as well as things like cardboard concrete forms: Sonotube(r)) and there is huge variability in dielectric strength. I would imagine that RF loss also varies substantially.

If you're really obsessing, the loss varies quite strongly with humidity. PVC readily takes up and releases moisture from the atmosphere.

"Geoffrey S. Mendelson" <gsm@cable.mendelson.com> wrote in news:slrni0vn5p.3ik.gsm@cable.mendelson.com:

Geoffrey,

I have bad news for you, your post is based heavily on misconceptions, archetypal ham myths even.

I wrote a short article entitled "A simple VSWR analysis without mirrors" at http://vk1od.net/blog/?p=1259 , which analyses a mismatched line example without resorting to dodgy concepts often (and almost exlusively) employed by hams. The article does deal with why there is a reflected wave, and the result of that reflected wave on line loss and transmitter loading.

IMHO, you would do best by starting with a reputable text book, and studying the topic. Certainly, the S/N ratio in ham forums is low, 'facts' seem to be determined by vote, and your wrong concepts are more likely to be reinforced than seriously challenged.

Owen

Its radiated, less losses.

> If you are designing a tuner, where would you design it to go?

That would depend upon desired system characteristics.

> Thanks in advance
>
> Geoff.
>

A antenna at resonance does not necessarily match the feeder impedance !
The whole idea of a tuner is to make one end match the other.
Stating a VSWR of unity implies a 50 ohm measurement system, which an
antenna at resonance rarely is.

All of the power produced by a transmitter is either radiated or dissipated as heat, period. But you'll never understand where the "reflected power" goes until you understand where it comes from.

Consider a 100 watt transmitter connected to a 50 ohm dummy load or antenna via a half wavelength of 50 ohm lossless transmission line.

The transmitter sees an impedance of 50 ohms resistive.
The transmitter delivers 100 watts to the transmission line.
The transmission line delivers 100 watts to the load.
The load dissipates 100 watts.
The VSWR on the line is 1:1
The "forward power" in the transmission line is 100 watts.
The "reverse power" in the transmission line is zero.

Ok so far? Now replace the transmission line with one having 200 ohm impedance.

The transmitter sees an impedance of 50 ohms resistive.
The transmitter delivers 100 watts to the transmission line.
The transmission line delivers 100 watts to the load.
The load dissipates 100 watts.
The VSWR on the line is 4:1.
The "forward power" in the transmission line is 156.25 watts.
The "reverse power" in the transmission line is 56.25 watts.

By changing the line impedance, we somehow created an extra 56.25 watts of "forward power". Neither the transmitter nor the load was aware of this wonderful event, since the transmitter sees the same load impedance as before, and the load sees the same source impedance. The transmitter is delivering exactly the same amount of power as before, and the load is dissipating the same amount. (If the transmission line had loss, it would have increased very slightly, but probably not enough to measure, and certainly much, much less than 56 watts.)

Likewise, neither the transmitter nor the load knows anything about the new "reverse power" which was created at the same time.

So the answer to your question is that the "reverse power" goes to wherever the new excess "forward power" comes from. Once you figure out where that is, you'll have a better understanding of the topic than nearly everyone who has been arguing on this forum about it for years.

As for a tuner, it has the magical property of having different amounts of "forward power" and "reverse power" at its input and output when the amount of actual power flowing is the same on both sides (neglecting tuner loss). So it can create or destroy "forward power" as well as "reverse power" by a simple twist of its knobs. Little does the tuner, transmitter, or load know that as soon as "reverse power" is created, interminable arguments will take place debating about where it goes.

I now return you to your regularly scheduled programming. . .

Hi Geoff,

You would put it closer to the antenna.

>If you connect a tuner and it is "tuned", none of the power is reflected
>back to the transmitter.
>Obviously it has to go somewhere.

From the perspective of the transmission line in between, when it hits the discontinuity of the tuner, it is reflected back to the antenna. The antenna drains away some of that power (just as it did in the original pass). The process repeats (the antenna is still partially reflective) and is further sustained with new cycles of energy.

There are finer details that shift these dynamics.

Differentiate between an antenna that happens to present the wrong non-reactive resistance... the tuner is just a transformer (whether done with linked magnetic fields, or by a narrow band matching network of Ls and Cs)

and an antenna that presents a reactive feedpoint impedance.
In this case: energy circulates between the tuning network and the antenna.

Say your antenna presents a Z that is inductive and you put a parallel capacitor across the feed to exactly cancel the "inductance". What's really happening is that you have the equivalent of an LC tank where the energy moves back and forth between L and C every cycle. In the classic LC, the energy moves between the magnetic field of the L and the electric field of the C. In the antenna case, it's somewhat more complex: the antenna stores energy in the near field in both electric and magnetic fields.

That answers the question...
The problem is that nothing is lossless, so as it moves, there's a loss. If it's a resistive loss, it goes as I^2, so doubling the current results in 4 times the loss. And, if you have an antenna with high stored energy (about which more, later), this square of the current means bad news.

Many antennas don't have an explicit separate matching network, but do the cancelling by doing it within the antenna structure: say by changing element lengths, etc... so now that "circulating current" is circulating between different parts of the antenna.

In fact, the ration between that stored energy and the amount flowing "through" (i.e. radiated away) is related to the directivity of the

antenna: high directivity antennas have high stored energy (large
magnetic and electric fields): the ratio of stored to radiated energy
is "antenna Q" (analogous to the stored energy in a LC circuit leading
to resonant rise).

So, high directivity = high stored energy = high circulating energy =
high I2R losses.

It circulates between tuner and antenna.

Hi Jim

Even 101 nylon has a problem like that. When you machine it after its been sitting on the shelf for a few months you find the diameter has increased from water absorbtion.

Cheers Bob

> identical pulses would you see the same lack of energy transfer?

Of course not, because then there would be. And the measurement of
voltage and current would show it to be so. P=3DVI holds.

If one selects a V and I that are not appropriately related then one
does not compute a useful power, though the units may still be J/s.
As an illustrative example, if I measure the voltage across my stove
and the current through my light, I can multiply them together to
get watts, but it does not mean much.

> A linear system, where superposition applies should not change based on
> minor changes to the signals in it.

Agreed. The computations done with the altered signals will
successfully
predict the altered outcome.

> Limiting any analysis to steady state sine waves or uniform pulse trains
> may cause you to reach the wrong conclusions

Yes, and no. I suggest that the models that are claimed to
successfully
predict the behaviour for sinusoids should also successfully predict
the
behaviour for simpler examples. Otherwise the models are suspect. So I
use the simpler examples to show that the models break down.

Ahhh, so you are only claiming that 'on average', the energy does not
enter the PA or 'on average' the energy is reflected.

The finer grained time domain analysis, reveals that some energy does
enter the PA, but that it comes back out again to keep the average the
same.

So if you want to live with the coarser, less complete models, that
is
fine as long as you understand the limitations of your model. It would
be good if you were to articulate these limitations to the readers
to reduce confusion.

Of course, if you are happy with averages, it is not obvious to me
why you want to bother with separating the signal in to forward
and reflected. Why not just use the overall average energy flowing
towards the load.

Not quite. It does not apply to power because it does apply to
voltages.
If one doubles the voltage, one gets 4 times the power. There is no
way to make superposition (which is simply addition) simultaneously
work
for voltage and power.

As for scalars... Superposition works quite fine for circuit analysis
with scalars.

Superposition is a mathematical trick that allows the solution of
the problem. It does not mean that the pulses pass through each
other, though that is one of the visualizations. Consider a point
on the line where the current is always 0, no electrons cross
this point nor does any energy. Did the pulses cross through
such a point? The voltage envelope appears to, but does that mean
the pulse did?

I have no issues with the applets. They show voltage waves crossing
each other and appropriately use superposition to derive the results.

Like many optical illusions, there are multiple ways to visualize
what is happening. The second one for example can also be seen as
the two pulses bouncing off of each other. The response would be
identical if the transmission line was cut at the point of collision.

These two simulations do not claim to show energy moving all the
way down the line in both directions, nor do they superpose powers.
So they look fine.

...Keith

Hello Keith:

I believe I just understand where is the problem You are talking
about "Superposition Theorem" of circuit theory and we are talking
about "Superposition pinciple of waves". There are not the same stuff.
Please read this page from "Physics for scientists and engineers with
modern physics" book to aliviate my translation :>)

http://books.google.com.ar/books?id=3DwQCMC3ryYzkC&pg=3DPA501&lpg=3DPA501&d=
q=3D%22superposition+principle%22+%22traveling+waves%22+physics+-quantum&so=
urce=3Dbl&ots=3DSK0b7V6O6y&sig=3DHzwcgc2DJnXKce2QZliOYq8yhDw&hl=3Des&ei=3D-=
2AQTLqpM8P98Abx_ciFBg&sa=3DX&oi=3Dbook_result&ct=3Dresult&resnum=3D5&ved=3D=
0CDUQ6AEwBA#v=3Donepage&q=3D%22superposition%20principle%22%20%22traveling%=
20waves%22%20physics%20-quantum&f=3Dfalse

Uf, what a large link!! If do not works search on page 501 of Google books with the appointed title.

Note =3D> "Two travelling waves can pass trough each other without being destroyed or even altered". (Op. Cit.). (Please pay attention to pond example).

The applet there do not represent an opticall illusion, You can experiment with different shape opposite end launched pulses in a rope to verify that do not collide but pass through each other. It is a usual student laboratory work on applied physics.

73

Miguel ghezzi LU6ETJ

PS: Yes Richard I live outside of Buenos Aires city. I hope you have been welcome on your visit to Argentine... and... what do you think of our beautiful girls, ah? ;>D

Before I forget... Here is early mornig and I am ready for bed (I'm nocturnal habits). I want give a QSL to Cecil's comment on Maxwell article and Joe's example in CC. Also, noblesse oblige, I recall that Cecil make this comment in a very early post in this thread:

> Yes, standing waves are hard to visualize, but there is indeed
> same- cycle interference involving forward waves and reflected
> waves. There is a certain delay from the source signal to the
> load and back that can be calculated if one chooses. The
> wave reflection model is closer to Maxwell's equations than
> is the lumped-circuit model where EM waves propagate
> instantaneously.

Pointing to differences between lumped constants circuit theory models (superposition theorem) and TL issues. I aknowledge his linked page
=3D>
http://www.google.com/url?sa=3DD&q=3Dhttp://www.ttr.com/corum/index.htm&usg=
=3DAFQjCNGKvyE7gzlWnW7706V-3Vix1MXnrA
where it said:

"There are no standing waves on a lumped element circuit component. (In fact, lumped-element circuit theory inherently employs the cosmological presupposition that the speed of light is infinite, as every EE sophomore should know. See, e.g., - Electric Circuits, by J.W. Nilsson, Addison-Wesley, 1983, p. 3.)"

Probabily Cecil had in mind this controversy when I submitted my question to this newsgroup. He will correct me if I am wrong.

Thank you very much, and now, I am go to ZZZZZZZ...!

Miguel

Ah! Cherchez la femme. We did a lot of walking around town (stayed in the Emperador across from Estaci�n Retiro) and there were certainly crowds of them on Av (Calle?) Florida and along Av 9 de Julio (24 lanes of traffic as I remember with trying to cross from the Opera house Teatro Col�n). In the back of my mind was that Buenos Aires enjoys the world's highest pedestrian death rate. One large truck replaced it horn with the sound of someone screaming. (The memories are starting to flood back.)

It was strange to see Spanish headlines about the capture of Saddam Husein in his spider hole. An out-of-America experience much like the evening when I was standing on the quay in Acapulco, waiting for the Liberty launch back to my ship, and a wave of talk spread through our group that Nixon had just resigned.

However, returning to pretty girls, when I was in Caracas ten years ago, I was told the poor lived up in the hills that surround the city like a fish bowl and the girls got plenty of exercise climbing them.

Gave them Miss Universe figures.

As for Buenos Aires hospitality, too much food (huge steaks) at the wrong hours. When we went to a restaurant at 9PM, it was like we were arriving for high tea. How gauche of us. Later, we were satisfied to enjoy empanadas in the late afternoon and call it dinner. We also took the train from Estaci�n Constituci�n down to La Plata to see the Catedral. Dinner nearby was Wiener Schnitzel. Enjoyed walking through Recoleta (and seeing the cemetery). Also got out to Abasto to see Carlos Gardel's neighborhood (love his Tango, his singing gets better every year).

It was great!

Let's be careful to point out that "forward power" is a measurement *at a fixed point* on a transmission line of the rate of flow of the forward energy which is traveling at the speed of light in the medium. Same concept for "reflected power" - reflected energy flowing in the reverse direction at the speed of light in the medium. EM waves cannot stand still.

It's easy to figure out where the excess forward energy comes from especially in an ideal lossless system which I will assume for the rest of this posting. Consider the following thought experiment. An ideal lossless system with a one-second long Z0=3D300 ohm feedline. Why one-second long? Because the watts (joules/second) and the joules will be the same magnitude, i.e. If it's a matched line with 100 watts of forward power, it is easy to show that a one-second feedline has 100 joules of energy in it that has been sourced but not yet delivered to the load - like a delay line.

Here's an example of a Z0-matched system with an SWR of 6:1 on the Z0=3D300 ohm feedline. *Steady-state* conditions are: forward power =3D 204 watts and reflected power =3D 104 watts. Power delivered to the load =3D 100 watts. There is a steady-state Z0-match at '+'. Zero reflected energy reaches the source, i.e. the SWR on the 50 ohm line is 1:1.

100w source---50 ohm line---+---1-sec-long 300 ohm line---50 ohm load

During the transient key-down state, the source supplies a number of joules to the transmission line that do not reach the load. At the beginning of steady-state that value is 204 joules plus 104 joules equals 308 joules.

When steady-state is reached there are 308 joules of energy "stored" in the one second long transmission line that have not been delivered to the load. Only after the transmission line is charged with steady-state energy does the load start to accept the same amount of power as is being sourced. There is no magic here - just a simple accounting for all the energy. Why otherwise intelligent, educated RF engineers cannot perform that simple second-grade math is a subject for another thread.

During steady-state, there are 308 joules of energy "stored" in the transmission line that are performing the Z0-match function. There are 204 joules in the forward wave and 104 joules in the reflected wave. Since RF cannot actually be stored as in a battery, this energy is moving at the speed of EM waves - the speed of light in the medium. 104 joules/second is continuously being reflected at the load. 104 joules/second is continuously being redistributed back toward the load at the Z0-match.

At key-up, steady-state ends and the key-up transient state occurs. During this transient state, all of the 308 joules in the forward wave and reflected wave during steady-state will be dissipated. During the key-down transient state, 308 joules are stored in the one second long transmission line. During the key-up transient state, the 308 joules are dissipated. For those who feel overwhelmed, it is just simple second-grade math

In a Z0-matched system, the entire analysis can be performed using an energy analysis instead of a voltage analysis. The common way to analyze the above system is to assume that 70.7 volts is present on the 50 ohm side of the Z0-match with 1.414 amps flowing into the Z0-match. But with only an energy analysis, we can reverse-engineeer the voltage and current conditions at any point in a Z0-matched system.

Fact of Physics: There are exactly enough joules of energy in the mismatched transmission line to support the forward wave power and the reflected wave power. It's not magic nor rocket science. Anyone willing to count the joules that have not reached the load will realize that the energy in the forward and reflected waves consists of real-world joules that cannot be swept under the rug just because some alleged RF guru is ignorant of the laws of physics.

Here's a simple math problem for all of the readers having trouble with this concept. On 10 MHz, we have a 50 ohm antenna being fed with one wavelength of lossless 300 ohm line from a 100w source. During steady-state, how many microjoules of energy are "stored" in the transmission line that have not yet reached the load? How are those microjoules split between the forward wave and reflected wave?

Just a nit: A certain magnitude of energy circulates between tuner and antenna. Experiments with TV signal ghosting prove that it is not the identical energy, just the same magnitude of energy.

http://www.w2du.com/Appendix09.pdf

A purist might argue that, like a lossless transmission line, an ideal conjugate match cannot exist in reality because of resistive losses and non-linearities.

What might be a more accurate statement is: By definition, Walt's data supports the evidence of a real-world Conjugate Match. Walt has

```
certainly defined in detail what he means by a "(real-world) Conjugate
Match".

Keith, virtually everyone (except you) knows that English is a contextual language and that the entire context cannot be repeated every time a sentence is uttered. You know and I know that the context is EM waves. The obvious context of my statement is: "It is invalid to try to use EM wave superposition on scalar values, since scalar values are not EM waves."

If you feel forced to resort to crap like that, it indicates that you have already lost any argument.

On Jun 9, 9:29=A0pm, Keith Dysart <keith.dys...@gmail.com> wrote:

> Ahhh, so you are only claiming that 'on average', the energy does not enter the PA or 'on average' the energy is reflected.

Of course, you already knew that because I have never said otherwise. I have stated my opinion more than once that instantaneous (virtual) power is not worth discussing. Here is what I said on my web page:

"Please note that any power referred to in this paper is an AVERAGE POWER. Instantaneous power is beyond the scope of this article, irrelevant to the following discussion, and "of limited utility" according to Eugene Hecht. [4]"

I have an ample library and cannot find any reference to instantaneous (virtual) power other than it is "of limited utility", as Hecht noted. Most of the references imply that paying close attention to the reality of instantaneous (virtual) power can lead one down a primrose path to false assumptions.

> The finer grained time domain analysis, reveals that some energy does enter the PA, but that it comes back out again to keep the average the same.

So what? If it is not dissipated or radiated, it doesn't matter to anyone (except you).

> It would be good if you were to articulate these limitations to the readers to reduce confusion.

I have always said that I was talking about power dissipation in a source resistor or load resistor (or radiation), but you already knew that. I have said that instantaneous virtual power is irrelevant and not worth discussing.

Here is a question for you. Given that P(t)=3DV(t)*I(t), we measure 10 watts at each of 10 points within a single cm., five just inside a source and five just outside the source. Does that mean we have 100 watts in that single cm.? What is the physical meaning of being able to measure an infinite amount of power given an infinite number of measurement points?

It probably should have said: "By a (possibly invalid) definition only, there are no standing waves on a lumped element circuit component, even though standing waves might exist in reality". Note that Dr. Corum is NOT saying that there are no standing waves. He is simply repeating the false assumptions of the lumped-element circuit model. In his other paper, he says that if a circuit is electrically longer than about 15 degrees and phase is important, the lumped-element circuit model should not be used.

Any lumped-element circuit analysis can be caused to fail simply by increasing the source frequency.

You wrote:
"You can use any insulated wire"

I agree.
I hound in tracing the location of large buried undrground pipelines, the "cooperative method", a transmitter attached to the pipe with a receiver sensing the signal on the pipe worked best. Due to ground characteristics, the lower the frequency, the better. I used 12 Hz.

My transmitter used cpmplementary symmetry power transistors in its output which fed a 400-Hz Variac which proved to work well as a variable impedance matching transformer to the pipeline. Oscillator-amplifier and Variac were about the size of a bread box and weighed much less than the 12-volt car battery which powered them.

The receiver was a common relay coil with an iron core which fed a transistor amplifier which had its output rectified and metered. The coil was attached to a stick which served as a wand. Divers used the coil in rivers and oceans where it followed the signal very well, as on land.

The strongest signal was when the core pointed directly to the pipe, and checking the distance to either side of the pipe the signal could be well received gave an estimate of the depth of the ground covering the pipe, usually 6 to 8 feet in our case. I could go miles down the pipe before the signal faded (once 8 miles).

I don`t know how applicable any of my pipeline experience is to animal burrows but it works well with tracing buried conductors or wires in walls for that matter.

Our pipelines also had rectifiers for cathodic protection and I also keyed these on and off at low frequency to provide a unique signal to follow.

Best regards, Richard Harrison, KB5WZI

only in the very special case of the far end being an open or short
circuit and the line being lossless. simulate it for a more general
case of a load other than those and see what happens.

only as you monitored the initial transient. once the transient has
passed there is no power flowing in the line. to drive power requires
a potential difference, without potential difference there is no
current and no power.

>
> > in this simple dc case

> or pick your waveform. There is no magic related to AC.

ah, but there is... in a sine wave the voltage never stops changing so
there is always a potential difference driving the wave along the
line. with DC you can reach equilibrium in one transit of the cable,
assuming it is lossless and the source and/or load is matched to the
line. otherwise you have to do the infinite sum to approximate the
steady state as for any other transient. complex waveforms get ugly
since they are infinite sums of sine waves, though for lossless and
dispersionless cables they aren't too hard to handle. The magic of a
single frequency AC source is it lets us use simplified equations that
make use of the sinusoidal steady state approximations... this is what
lets us do things like s parameters, phasors, E=3DIZ, and cecil's simple
power addition equation, without the need for messy summations and
other more detailed calculations.

> the AC analysis begin to fail?

none, there is no magic cutoff, its just how close you want to look at
it.

>
> > now you have to go back to the general equations

true, another simplification made possible by the sinusoidal steady
state approximation.

> but
> reflection coefficients and the the computation of forward and
> reflected voltages, currents and powers are waveshape independant.

only as long as the loads are perfectly resistive and linear. real
loads often change impedance with frequency and so distort the
reflection of complex waveforms. use a scope with a good risetime and
a decent fast rise time pulse and you'll see it.

>

Real loads also change Z with power - especially dummy loads. As a
real load has some trait of dummy load in it (loss) the degree of Z
change is in the degree of temperature change.

Hello folks. (I am learnig new greetings...)

Hi Cecil:
Yesterday I was making some calculations based in your article "An
energy Analysis of a Simple Ideal Source, Part:1 Zero Average
Interference"
I have checked your and Roy results using three methods: Mathematical
solution using the TL Zin obtained from cl=E1ssical formulas.
Spice simulation with equivalent lumping element resulting of the
above cited formulas, and Spice simulation with a RG8U TL loaded with
RL's of your and Roy examples..
In all cases results agree between different methods and with your
examples (I do.not want to seem pedantic with this last comment ;>))

For this discussion would be relevant the results corresponding to
sixth column of your article using a quarter wave line.
They are: 0 - 8 - 22 - 50 - 88.9 - 128 and 200 W (190 W the last one
with Spice TL simulation).

Since the refflection coefficient has not changed, if I do not

misunderstood the premises, quarter wave line PRs do not seems agree with the hipothesis of Pref adding in Rs with Pfor. I think that is what Ro. Lewallen denote in his "Food for thought: Forward and reverse power" example.
Frankly, I think there are somthing wrong in my interpretation because you (all) should have already performed these checks. I remember you have said something about that your work (article) was not finished yet. I confess actually I have not yet entirely clear your differences but I hope to capture it more accurately.

73 - Miguel LU6ETJ

PS: Hey Richard, I'm glad you liked our city, girls and steaks :>) well you like Gardel (me too) and I like so much your old and classic jazz music. Billie Holiday... she is one of my favorites.
A friend of me living in Caracas now tell me the gift of fifteen for girls consists of the operation to put silicones. must be very dangerous for heart patients, a lot more dangerous than Buenos Aires street traffic ;>)
(SRI, I can not translate =3D> "waiting for the Liberty launch back to my ship", give me a hand PSE)

Hi Miguel,

I was in the Navy from 1968 to 1975. Our president Richard Nixon resigned from the presidency in 1974. My ship was in transit between Charleston, South Carolina to go to the naval ship yard for overhaul in Bremerton, Washington (state), near Seattle (where I live).

On the way, we spent 5 days in the harbor of Acapulco. We were "anchored out," which means resting at anchor in the bay instead of tied up at a pier.

The only way to get back and forth was by a smaller boat (carries about 75 people). That boat is called a launch. That name is qualified with Liberty because those who used it were going on Liberty. In the Navy, Liberty means "time off" or "free time," which means we can leave work and do what we want to until 0800 the next day. If we have to be back by midnight, it is called "Cinderella Liberty."

I was one of the senior Metrologists in the Fleet Electronics Calibration Laboratory aboard the USS Holland, AS-32 (now tied up in retirement in Bremerton). I did precision measurement and calibration of RF standards and maintained a Cesium Beam Standard (atomic clock) that set the time for the "Boomers" (nuclear submarines). Later, after the Navy, I added physical standards (length, pressure, tension, temperature, torque, smoothness, incline...) to my resum�.

I try to catch as many movies from Argentina as possible (I like Ricardo Dar�n as an actor, and love "Nueve Reinas"). One of my degrees is Cinema (the other is English). Another title I like (since it is about an out-of-work programmer) is "Una Sombra ya Pronto Ser�s." Sometimes that title works here too. H�ctor Olivera, the director, has done some interesting things.

Could you or someone please post the same analysis when the electrical length of the 200 ohm transmission line is 1/4-wave rather than 1/2-wave, including the physical locations/components where r-f output power is dissipated?

RF

this is a relationship i haven't heard of before... and would be very
wary of stating so simply. it may be true for a specific type of
antenna, MAYBE Yagi's, MAYBE rhombics or or close coupled wire arrays,
but some of the most directive antennas are parabolic dishes which i
would expect to have very low Q and extremely low losses. you could
also have an antenna with very high Q, very high i^2r losses, but very
low directivity, so i would be careful about drawing a direct link
between the two.

Well Richard, since the example discussion implies lossless line, you know that zero power is dissipated in line losses.

Assuming that you are talking steady state...

If literally, you changed the line length in Roy's example to an electrical quarter wave, then the transmitter will see a load impedance of 800+j0, and it will develop exactly the same power in the actual load (quarter wave 200 ohm line+50+j0 load) as it would in a 800 ohm resistor connected to its output terminals. Since the line is lossless, 100% of the actual transmitter output power is absorbed by the load, dissipated if the load was a resistor. If you were to plot the instantaneous power at the transmitter output terminals vs time, it would always be positive, ie there would not be a reactive component.

The transmitter output power is probably different to that developed in a 50+j0 load for several reasons, but there is not enough information to determine that output power.

Of course, a practical line has line loss, and the heat generated under standing waves varies along the line (ie W/m is not constant), and the impedance seen by the transmitter will be a little different (including being reactive) due to the fact that Zo is not real, the VSWR is not 4, and effects of line attenuation, so actual transmitter power may be a little different.

Owen

Thank you, Owen.

Do your comments apply to a transmitter designed/adjusted for, and
expecting a 50 + j 0 ohm load?

IOW, if the net output power of such a transmitter (which equals that
dissipated in the load) probably is different with such a mismatch, do
you expect the reason for that to be related to "reflected power?"

I'm sorry, Miguel, using a "quarter wave line" is a mistake. You should be using a lossless 1/8WL line. The results in my article are based on a 1/8WL (45 deg) lossless line, NOT on a 1/4WL (90 deg) line. *Please re-run your Spice simulation using a 1/8WL line* and report back to us. When the line is 1/8WL long, the reflected wave arrives back at Rs 90 degrees out of phase with the forward wave and cos(90) =3D 0, so the interference term is zero and all the reflected power is dissipated in the source resistor. For the special case where cos(A)=3D0, i.e. the interference term is zero, the power density equation reduces to: Prs =3D Pfor + Pref + 0

Nowhere in my article did I use a 1/4WL line so please don't say that your Spice results disagree with my chart. It is perfectly understandable that your 1/4WL results do not agree with my 1/8WL results.

NO! NO! NO! the difference is not due to 'reflected power'... any difference is due to the impedance change seen by the transmitter at its terminals.

A VERY important method of analyzing sinusoidal steady state response of a system like a transmission line with a load on the end takes the load impedance and transforms it using the transmission line equations (with or without loss) back to the source terminals and then replacing it with an equivalent impedance. as long as the load is constant and linear this is a well known and easily proved substitution. you can then solve for conditions seen by the source ignoring the length of the line and load and using only a lumped impedance, therefore any reflected wave is irrelevant when analyzing the response of the source.

If the "forward" power that can be generated by a transmitter is
dependent on the degree of match of the output load to the load
specified for that transmitter, would that not mean that there would
be little/no risk of damage to the transmitter if it was operated into
a load with ~infinite SWR relative to the load it expects, such as a
short or open directly at its r-f output connector?

this is a reasonable description of the derivation of these
techniques, study especially the Thevenin equivalent impedance
representation on page 2-13 and how it is applied:

Please let's be careful to give all the details. The *virtual*
impedance, the ratio of Vtotal/Itotal, seen by the transmitter at its
terminals is:

Z =3D Vtotal/Itotal =3D (Vfor + Vref)/(Ifor + Iref)

where all math is phasor (vector) math. Vref and Iref are components
of the reflected wave. So the mismatch is certainly related to the
magnitude and phase of the reflected wave. If the Z0 of the
transmission line is the impedance for which the transmitter was
designed, we can go as far as to say that the reflected wave causes
the mismatch, the virtual impedance that deviates from the Z0 of the
line. Before the reflected wave arrives back at the transmitter, the
transmitter sees the Z0 of the transmission line. The mismatch
develops when the reflected wave arrives.

i wouldn't call it a 'virtual' impedance, it is a very real impedance. it is the steady state impedance seen by the transmitter at its output terminals. once the transient response rings down the waves in the line beyond the terminals are irrelevant and the constant impedance can be used to calculate the voltage, current, and power in the source. in the steady state (which except in special cases is entirely adequate for amateur use) the mechanism of generating that impedance is irrelevant, waves or not it can be represented by a constant value and the source won't know the difference.

It can be very close, though, if the system is designed/optimized properly.

Below is a link leading to the r-f pulse measurement of a UHF TV broadcast antenna system that I made as an RCA field engineer some 35 years ago. The incident and reflected waveforms are very similar.

The Z-match of this antenna was optimized to the transmission line using a variable transformer at the input to the antenna, which antenna was installed atop a ~ 1,500 foot tower (note the ~3 =B5s round trip for the reflection, at ~492 feet/=B5s).

The H.A.D. of this sin^2 pulse denotes an r-f bandwidth approximately as great as can be carried by a 6 MHz analog US TV channel.

On Jun 11, 10:36=A0am, K1TTT <k1...@arrl.net> wrote:

> i wouldn't call it a 'virtual' impedance, it is a very real impedance.

Yes, it meets the (B) non-dissipative definition of impedance from "The IEEE Dictionary". It doesn't meet the (A) dissipative definition and it is not an impedor as it only exists as a V/I ratio. That's why I call it a virtual impedance. There is no resistor, there is no inductor, and there is no capacitor. There is only a V/I ratio caused by something else.

> it is the steady state impedance seen by the transmitter at its output
> terminals. =A0

And it is a V/I ratio caused by the superposition of the forward wave and reflected wave, i.e. it would NOT be the same impedance without the reflected wave. That fact of physics is undeniable.

When we have an actual impedor, i.e. a resistor plus an inductor or a capacitor, the voltage/current ratio is caused by the impedor. When we have a virtual impedance, the cause/effect procedure is reversed and the impedance is caused by the voltage/current ratio which may (or may not) contain both forward and reflected values.

For the two definitions of impedance, (A) and (B), given in "The IEEE Dictionary", cause and effect are reversed.

Let's take an example. Assume a 50 ohm load resistor fed with 1/2WL of 300 ohm lossless line. If we assume a 100 watt (50 ohm) source, the forward power will be 204 watts and the reflected power will be 104 watts.

100w Source----1/2WL 300 ohm feedline----50 ohm load

In the feedline, a forward power of 204 watts is a forward voltage of 247.3 volts and a forward current of 0.825 amps.

In the feedline, a reflected power of 104 watts is a reflected voltage of 176.6 volts and a reflected current of 0.589 amps.

The reflected voltage is 180 degrees out of phase with the forward voltage at the transmitter, so the superposed voltage at the transmitter is 70.7 volts. The reflected current is in phase with the forward current at the transmitter so the superposed current is 1.414 amps. Since everything is either in phase or 180 degrees out of phase, phasor addition is not needed. So I repeat, the impedance seen by the transmitter is:

Z =3D (Vfor - Vref)/(Ifor + Iref)

Z =3D (247.3 - 176.6)/(0.825 + 0.589)

Z =3D 70.7/1.414 =3D 50 ohms, NON-DISSIPATIVE!

It is clear that the superposition of the forward wave with the reflected wave is the CAUSE of the 50 ohm impedance. That particular impedance cannot exist without the effects of the reflected wave.

Using a math model for answers to problems for so long that one comes
to believe that the model dictates reality is a major contributor to
the myths and old wives' tales that exist in amateur radio today. It's
time to get back to the basics even if it causes a few old rusty
brains to be put in gear for the first time in decades.

We've had this discussion many times before, but with no apparent change in your perceptions of the nature of "reflected power".

But why would you expect the "reflected power" to have a different effect when the transmission line is a quarter wavelength than when it's a half wavelength? Can you write an equation giving the supposed dissipation caused by "reflected power" as a function of transmission line length?

Roy Lewallen, W7EL

If reflected power is fictitious, and the number wavelengths of
transmission line of any random impedance compared to the load
connected to it makes no difference in the load seen by the
transmitter, the output power produced by the transmitter, and the
power dissipated in the far-end termination, then what is the reason
you chose a 1/2 wavelength of transmission line in your quoted post?

Well, we will see in a couple of weeks what I get. I broke down and bought
a set consisting of a BNC crimping tool, a wire stripper and 50 rg-59
BNC plugs from an eBay store.

They did not have any rg-6 plugs, so I'm hoping that the RG6-QS I've got
works.

It's the heavy duty kind that looks like a heavy duty side crimp tool, except
that the wire goes in the top and the plug is pushed together from the handle
end (bottom).

I'll report back.

Thanks for all the help and support so far.

Geoff.

>The 100W forward and 50W reflected have no relation to actual powers

From HP Journal V.7n.2:

If an incident wave is applied at the left as shown in the diagram, the wave passes down the main arm. In the region where the lines are coupled, a wave 20 db below the incident wave will be coupled to the "Forward" terminal, while a second wave 20 db below the incident wave will be coupled to the resistive termination in the "Reverse" arm.

Since the combined power in the two split-off waves amounts to only 2% of the power in the main wave, the main wave is essentially unaltered and continues to the right-hand terminal.

A wave applied at the right end of the coupler is coupled in an analogous manner. Waves 20 db below the left-traveling wave will be coupled to the "Reverse" terminal and to the resistive termination in the "Forward" arm, while the main part of the wave continues to the left-hand terminal.

The couplers thus provide equal fractions of right-traveling and left traveling waves at separate terminals. The ratio of these waves will be equal to p *, the magnitude of the reflection coefficient of any device connected to the output of the coupler. This ratio can be measured (Fig. 4) by applying the outputs of the "Forward" and "Reverse" terminals to the -hp- 416A Ratio Meter, using suitable detectors to demodulate the amplitude-modulated power which must be used with the system.

In an ideal directional coupler, no power from a forward wave would be received at the reverse terminal and no power from a reverse wave would be received at the forward terminal. In practice some undesired

power is received at these terminals,
although it has been possible to de
sign the couplers so that this unde
sired power is at least 46 db below
the parent wave, i.e, at least 26 db
below the desired wave at the oppo
site terminal. In other words the di
rectivity of the couplers is at least
26 db (30 db in the lower frequency
couplers) over the complete fre
quency range [Fig. 3(a), (b)].
The coupling mechanism itself
consists of quarter-wavelength sec
tions of the conductors placed suit
ably near one another to achieve the
desired degree of coupling. The
combined effects of electrical and
magnetic coupling impart directiv
ity to the coupled wave. The unused
terminal of each of the auxiliary
arms is terminated in a special widerange
low-reflection resistor to ab
sorb any power coupled to that ter
minal.

Again Wim, we're not on the same page, so let me quote from your
eariler post:

"Virtually all high efficient amplifiers work in voltage saturated
mode
and are therefore not operated at maximum available power, therefore
their output impedance doens't match the expected load."

I have not been talking about MAXIMUM available power, only the power
```

available with some reasonable value of grid drive. In the real world of amateur radio operations, of which I'm talking, when we adjust the pi-network for that given drive level, we adjust for delivering all the AVAILABLE power at that drive level. When all the available power is thus delivered, the output source resistance equals the load resistance by definition. We're now not talking about changing the load, phase or SWR--we're talking about the single condition arrived at after the loading adjustments have been made.

And Tom, why would the source be reactive when the pi-network is tuned to resonance? And because the source resistance of the (tube) power amp is non-dissipative, its reflection coefficient is 1.0 by definition, and so it cannot absorb any reflected energy, and therefore re-reflects it.

>The 100W forward and 50W reflected have no relation to actual powers

From HP Journal V4n5-6:

The multi-hole coupler design has now
been extended to a 3 db coupler, that is, a
coupler in which half the power entering the
main guide is coupled into the auxiliary
guide.
...
The -hp- multi-hole couplers consist of
two sections of wave guide mutually coupled
by two rows of coupling holes (Fig. 2).
Power entering the input arm of the coupler
flows down the main guide and divides at the
coupling mechanism. Part of the power con
tinues down the main guide where it will be
incident on any device connected at the end
of the guide. The other part of the power is
coupled into the auxiliary guide. It is a prop
erty of directional couplers that the power
coupled into the auxiliary guide flows essen
tially in only one direction. In the -hp- coup
ler, this power flow is in the same direction
as the power in the primary guide.
...
REFLECTOMETER SET-UP
...
Two directional
couplers are connected back-to-back
as shown.
****
I will leave it to the readership to imagine why.

What's the item number?  I'll check if you bought the correct
connectors for RG-6a/u QS coax.

```

point of reference in this newsgroup
Nothing personal Richard, but it is obvious that engineers are totally
split as to what theorem is correct and the one to be used. There is
no way
you will get agreement if they all insist their position is correct
and thus other positions are not worth consideration.You may be
correct in your position but the idea of change is not in your favor.

Thanks.

380197598600

Though to be honest, if they are not the correct ones, I'll still probably
use them anyway.

Geoff.

I don't think you can use them. Those connectors won't fit RG-6a/u
QS. Different outer diameter and center conductor diameter. The
RG-59 is slightly smaller than the RG-6QS.   The RG-6a/u QS will most
likely not even fit into the connector.

Note the difference:
<http://www.firefold.com/RG6U-Male-F-Compression-Connector-PPC-P2291C1145.aspx>
<http://www.firefold.com/RG59U-Male-F-Compression-Connector-P1966C1145.aspx>

Like I ranted, you should have gotten F connector and used adapters
such as this:
<http://www.firefold.com/BNC-Male-to-Female-F-Type-Adapter-P2782C1145.aspx>

The compression tool seems tolerable. However, I've had some
experience with the stripping tool. They work, but the blade

cartridge wears out rather quickly. My guess is about 30 connectors and it's gone. I use a thermal wire stripper at home and in the office, and my pocket knife in the field.

There are tools and connectors on eBay for RG-6:
<http://cgi.ebay.com/ws/eBayISAPI.dll?ViewItem&item=130343999448>

I like Thomas and Betts Snap-n-Seal connectors:
<http://www-public.tnb.com/ps/endeca/index.cgi?a=nav&Ne=3951&N=3949+950+4294951388&Ntt=&more=1&nk=3951>
<http://tnblnx3.tnb.com/emAlbum/albums//070%20Connectors%20USA/SNS%20Wall%20Chart%20Final%202009.pdf>
<http://www.tnb.com/contractor/docs/snapnseal.pdf>
Note that there are different connectors for RG6, RG6 QS, RG59 and RG59 QS.

>The 100W forward and 50W reflected have no relation to actual powers

From HP Journal V.3n7-8

DIRECTIONAL couplers have been used
widely in wave guide applications for
such purposes as monitoring power, meas
uring reflections, mixing, and for isolation
of signal sources. All of these applications
make use of the property that power flowing
in one direction in the main branch of the
coupler induces a power flow in only one
direction in the auxiliary circuit.

<keith.dysart@gmail.com> wrote:

>The 100W forward and 50W reflected have no relation to actual powers

From HP Journal V.6n.1-2:

Power from the source flows down the main arms of the two couplers (Fig. 2) and impinges on the load. The power split off by the 20 db forward coupler is all passed to the forward detector, since the directivity characteristic of the multi-hole directional couplers prevents any but a negligible amount of the splitoff power from turning back and being absorbed in the coupler's internal termination. The power split off the incident wave by the 10 db reverse coupler, however, is essentially all absorbed in that coupler's internal termination because of the reversed direction of connection of that coupler (Fig. 2).
If the magnitude of the reflection coefficient ~.T. of the load is, say, 0.1, Çf of the incident voltage will be reflected back toward the source. As this reflection passes back through the main arm of the reverse coupler, a 10 db split occurs and is applied to the reverse detector. The remainder of the reflection will proceed back toward the generator where it will be absorbed in the generator impedance and in the termination in the forward coupler.

****

Of course, in regard to this last sentence, HP engineers didn't know jack-shit about power reflections, especially what could be absorbed by the source.

These are known generically as "compression connectors", and I recommended the BNC type earlier, because when used with either a BNC-F on the antenna, or a BNC/N adapter to an N-F they are waterproof, and neither depends critically on the retaining nut torque for good electrical connection (as do UHF, SMA and F connectors). Compression connectors do not use a normal hex crimp tool, but a tool unique to themselves, and in the rest of the world, the tools are pretty inexpensive (<US20).

Whilst I say they are waterproof, with force, it is possible to break the front of the connector out of the connector body in the types that I have tested.

If you use ordinary (ie non waterproof) crimp BNCs, you need to figure some way to waterproof the cable jacket to the connector body. Most do not lend themselves to glue lined heatshrink for this purpose. Of course, you could always treat them like UHF series, and wrap the entire joint.

Owen

I have just read an article regarding an AR Op using a carbon fibre fishing rod to make a 12 foot mobile antenna for mobiling.

My question is, does carbon fibre absorb RF?

The operator has wound 5.2 metres (approx 17 feet) of insulated house wiring in a helical fashion around the rod. He uses an SG-237 tuner as well.

If indeed that carbon fibre is conductive, and he claims he is getting outstanding results whilst operating stationery mobile, then what is happening?

I would appreciate comments.
73.

Sine wave is an ideal wave. The motion to and fro are simmetrical.
In reality no such. The wave source push the medium strongly but it come
back with the lower intensity.
For this reason the wave flow transmits the energy from the source to
distant places.
In fluids take place also the mass flow.
S*

BNC's are still 50 or 75 Ohm. Old versions had different diameter
centre pins in order to acheive the correct characteristic impedance.

If you plugged a 50 Ohm plug into a 75 Ohm socket the larger centre
pin would splay out the female centre connector, so when you plugged a
75 Ohm back in again it wouldn't make contact. It used to be fairly
common practice to paint the body of the connector purple or green in
order to quickly identify the type and so prevent damage.

For the past 20 or so years most manufacturers have used the same
sized centre pin, but the 50 Ohm version has a PTFE skirt in order to
provide the correct charateristic impedance. So they are now
mechanically interchangeable.

Walt, this restriction was not given in the original posting, it is added by you and you exclude many other practical amplifier solutions (like push pull 3...30 MHz no-tune amplifiers, fixed tuned single band amplifiers, emerging high efficiency designs for constant envelope modulation schemes and/or AM with supply voltage modulation).

I fully agree with your statement on optimum matching given certain drive and output impedance in case of (pi-filter) matching, no doubt about this. However there are more flavors as I tried to explain.

Even during SSB modulation with an optimally tuned amplifier without power supply modulation, the amplifier is most of the time operated into current saturation mode (instead of optimally tuned output, given a certain drive). For tetrode/pentode, assuming no voltage saturation, the RF plate impedance is seldom equal to the conjugated load impedance (load impedance will be lower). I think for a triode in common grid operation, this will apply also because of the cathode is not grounded for AC, hence plate impedance increases. I have to be careful now to avoid that I have to do a lot of work to fulfill Richard's requests. I dismantled my PL519 common grid amplifier (<22 years ago), so a cannot measure it anymore.

All amateurs that do not have a tuner inside their PA, have to live with non-optimum VSWR (hence amplifier not operating at optimal tuning, even under CW) or have to insert a tuner. For the latter case, the problem now reduces to a cable and tuner loss problem, as after

successful tuning, there will be now power reflected to the PA, hence
the PA's output impedance doesn't matter.

Maybe the JC could provide some background behind his question.

In article <fda40c34-830f-438d-830e-0c1c23d2bc44
@c10g2000yqi.googlegroups.com>, ukmonitor@hotmail.com says...

> BNC's are still 50 or 75 Ohm. Old versions had different diameter
> centre pins in order to acheive the correct characteristic impedance.

Can you (or anyone !) provide some evidence of this, in terms of actual measurements or manufacturers' specifications showing a difference in the "Old" versions ? You are also confusing the effects of conductor diameter versus mating surface diameter. 75R and 50R STILL have different inner conductor diameters to achieve correct Zo; it's the MATING SURFACES which are the same.

> If you plugged a 50 Ohm plug into a 75 Ohm socket the larger centre
> pin would splay out the female centre connector, so when you plugged a

> 75 Ohm back in again it wouldn't make contact. It used to be fairly common practice to paint the body of the connector purple or green in order to quickly identify the type and so prevent damage.

I (professionally) used many thousands of BNCs during the timescale you mention. While it IS true that some 75R sockets could be damaged, in EVERY case it was due to the inner conductor of the plug being off-centre. 75R sockets were/are inherently rather fragile.
The problem was caused by a mechanical design weakness in some brands of plugs (I don't remember which manufacturers).
AFAIR, the BBC used 50R plugs/sockets in some 75R video equipment, simply because the 50R socket was more robust, by design.

> For the past 20 or so years most manufacturers have used the same sized centre pin, but the 50 Ohm version has a PTFE skirt in order to provide the correct charateristic impedance. So they are now mechanically interchangeable.

I have lots of old stock and recovered BNCs dating back at least 20 years. All the 50R and 75R components mate without problem.

Well I've got some old 75 Ohm female to female adaptors in front of
me, marked RS part number 455-933 (but the type associated with the
```

part number has changed many times over the years). I also have one marked G37534 which looks fairly similar. Most have been opened up because they have had a 50 Ohm shoved into them.

However on the one pristine 75 Ohm adaptor I could find, the outer part of the 75 Ohm centre receptacle is so narrow it would easily fit the inside of a 50 Ohm centre receptacle.

Unfortunately I can=92t find any old Greenpar (or similar) mechanical drawings on the web only the newer types.

UKM

I downloaded the mechanical drawings from the Amphenol web pile and
found that the center pin diameter is missing from the drawings.  I'll
look elsewhere when I have time.
<http://www.amphenolconnex.com/products/bnc.asp>

I have a box full of 75 coax patch cables I salvaged from a radio
station cleanup.  They all mate fine with a 50 ohm BNC jack.  The only
difference is that the 75 ohm plug has no dielectric, while the 50 ohm
jack does.

> And Tom, why would the source be reactive when the pi-network is tuned to resonance? And because the source resistance of the (tube) power amp is non-dissipative, its reflection coefficient is 1.0 by definition, and so it cannot absorb any reflected energy, and therefore re-reflects it.
>
> Walt, W2DU

If you allow that the thing driving the pi network has an effective source impedance different from the load that the pi network presents to it, then clearly the output impedance seen at the other end (the "50 ohm" end) of the pi network won't be 50 ohms. Try it with some numbers; for example, assume a pi network that transforms your 50 ohm load to a 4k ohm load to the amplifier output, and assume an amplifier output stage that looks like a 20k ohm source. Design the pi network for a loaded Q of 10. I believe you'll find that the source impedance seen by the 50 ohm load is about 11+j18 ohms.

As Wim has pointed out, requiring an amplifier to be loaded and driven in a very particular way unnecessarily dismisses some very important classes of amplifier. What do you do, for example, with a linear amplifier? What do you do with an amplifier that drives a voltage very hard (and for which a simple pi network is inappropriate for matching to a load)? Perhaps an even more basic question is: why exactly do we tune a pi network to present a particular load to an RF amplifier stage? Why should we operate a 6146 with, say, a 3000 ohm plate load? Why not 1000, or 6000?

And what if I set up a tube and pi network for operation such that the apparent output source impedance is 50 ohms (while driving a 50 ohm load), and then I add feedback to the amplifier in such a way that the operating conditions are not changed, but the impedance looking back into the plate is changed?

How did we get to the source resistance of "the (tube) power amp"

being non-dissipative? I know there are some of us who don't buy into
that...

Cheers,
Tom

Hello Walt,

I did some simulations with EL34.

Conditions:
Common Grid circuit, Valve connected as triode, 3.6 MHz.
Vsupply, 600V, Vgrid -58V, bias current 40mA (yes I know that it will
run very hot).

Maximum available input power: 9.2W out of 600 Ohms, sinusoidal.

Anode loaded with 20uH, 96pF, 3800 Ohms (parallel circuit), QL= 8.4, so the anode voltage has sinusoidal shape.

Without changing the drive (9.2W), 3800 Ohms with 96pF gives highest output power of 64W (Vanode = 698Vp). So power gain is 7.0.

Output impedance:
Change to 4100 Ohms load gives Zout = 1826 (voltage saturation),
Change to 3500 Ohms load gives Zout = 4350 (current saturation),
So for small change in Zload, Zout will be close the load resistor that gives maximum power. This supports that under well-matched conditions, given a certain drive level, Zout = ZLoad.

Input power reduced with 3 dB, output becomes 32.6W (Vanode = 497.5Vp, gain = 7.08). There is a slight increase in gain showing that at 64W the amplifier is not into deep voltage saturation.

Output impedance at 32.6W output:
Change from 3800 to 3500 Ohms gives Zout = 8100 Ohms.
This shows that reducing the drive level (without changing the matching) results in Zout not equal to Zload for this triode common grid circuit.

Also shown that small changes in load (reduction or increase seen at the anode) results in changes in output impedance. That is why I used three resistance values for determining Zout at well-matched output.
I used low frequency to avoid endless matching because of parasitic capacitances and I also skipped the output matching (I have to work sometimes, so time is limited).

It is not strange to see an RF swing above supply voltage as this is a common grid circuit with cathode grounded for DC.

If you like, I could do same exercise for modern amplifier topologies, but be prepared to see unexpected results (As Tom, K7ITM already noted).

Best regards,

Wim

On Jun 6, 4:58=A0pm, Roy Lewallen <w...@eznec.com> wrote:

> This is why, for
> example, a center loading coil must have more inductance than a base
> loading coil to effect the same change in reactance at the base.

The following is based on a fixed length antenna.

The phase shift at the top of each coil is associated with the abrupt shift in characteristic impedances at the coil-stinger junction (according to W8JI). When a base section is added to a base-loaded antenna, there is an opposite abrupt shift in characteristic impedance at the base-coil junction. That bottom (negative) phase shift subtracts from the (positive) phase shift at the coil-stinger junction so more phase shift must be added through the coil to compensate for the phase shift lost at the base-coil junction. Increasing the coil length provides the necessary additional phase shift.

Assume a loading coil has a characteristic impedance of 4000 ohms and the stinger has a characteristic impedance of 600 ohms at the coil-stinger junction. Given the impedance looking into the stinger, it is easy to calculate the phase shift at the coil-stinger junction. Let's (for instance) say the stinger's input impedance is 0.25 - j2500 ohms.

If we normalize that impedance to the assumed Z0=3D600 ohms of the
stinger, we get very close to -j4.167. The impedance at the very top
of the coil is the same and if we normalize to the assumed Z0=3D4000
ohms of the coil, we get -j0.625 ohms. If we subtract the arctangent
of those two values, we get the phase shift: 76.5 - 32 degrees =3D 44.5
degrees at the top of the loading coil. We can also read that same
value from a Smith Chart.

When we go to a center-loaded coil, the calculations are complicated
by the resistive portion of the impedance, but we will find a negative
phase shift at the bottom of the coil that subtracts from the positive
phase shift at the top of the coil. Since we have reduced the total
system phase shift by moving the coil to the center of the antenna, we
need to add more length to the coil to increase the phase shift
through the coil in order to compensate for the negative phase shift
lost at the bottom of the coil.

One can emulate the loading coil problem using pieces of transmission
line with different Z0s. The basics of shortened dual-Z0 stubs are
covered here:

http://www.w5dxp.com/shrtstub.htm

For instance, the following shortened stub has a resonant frequency at
which it is electrically 1/4WL long even though it is only 1/8WL long
physically because of the 45 degree phase shift between the two
sections.

-----22.5 deg 300 ohm-----+-----22.5 deg 50 ohms-----

What happens to the resonant frequency if we move half of the 50 ohm
line to the bottom?

----11.25 deg 50 ohm---+---22.5 deg 300 ohm---+---11.25 deg 50 ohm

How many degrees do we need to add to the 300 ohm line to achieve the
same resonant frequency as before?
Can anyone out there solve this problem?

David, you are preaching to the choir. I explained before that there
is NO interaction between forward and reflected waves because they are
traveling in different directions. The only time that coherent,
collimated waves can interact is when they are traveling in the same
direction in a transmission line.

Keith's argument requires that forward waves and reflected waves
interact. I say they cannot interact in a constant Z0 environment. You
say they cannot interact. We are on the same side of this argument.

The mechanism of the interaction of two coherent, collimated waves
traveling in the same direction is that the superposition process is
irreversible. The source photons and the reflected photons are
indistinguishable.

http://www.wbdg.org/ccb/FEDMIL/prf39012_16h.pdf is the MIL drawing for
the plug.
```

note they only have ONE drawing for the center contact.

They also call out MIL-STD-348 for the pin contact interface.
http://www.dscc.dla.mil/Programs/MilSpec/listdocs.asp?BasicDoc=MIL-STD-348
http://www.dscc.dla.mil/Downloads/MilSpec/Docs/MIL-STD-348/idstd348.pdf
is probably the one you want.

on the plug/pin, dimension C (the ID of the insulation inside the outer conductor) has a minimum, but no maximum.

Likewise on the socket, dimension E, which mates with dimension C on the plug does have a maximum, but no minimum, implying you can have a "no dielectric" version.

Dimension D on the plug (the pin diameter) has only one value 0.052 to 0.054 inches.

Dim M on the socket (OD of center conductor) is 0.081 to 0.089, presumably to correspond roughly with dimension R on the plug, which is the same.

Can you give measured data for the losses? (or reasonably high fidelity model data). I don't think the losses are *big* in either case, so you might be looking at the difference between 5% loss and 7% loss, which is negligible in the overall scheme of things.

I'd be willing to bet a six pack of frosty cold beverages (not the antenna) that it's not a 75% loss vs 10% loss situation..

Maximum current will be at the tuner which is not desirable.

yes and no. I don't think, on a short antenna (2 meters long, here, but let's say up to 3 meters) the difference will be significant;especially when viewed in the context that the whip is next to a big giant metallic object. They're ALL short compared to a wavelength, so the difference in ideal gain is going to be somewhere between 1.64dBi (infinitely short dipole) and 2.15dBi (half wavelength dipole)... And, given it's a (mostly) vertical antenna, for which you have no real control over the propagation path, who's to say that the fatter lobe on the infinitely short dipole might not be better than the slightly skinnier one on the half wavelength one.

(yes, it's a monopole..same idea though)

> The location of the loading coil has a large effect on the current
> distribution
> and efficiency of the antenna.

Quantify "large"...

Is it bigger than 3 dB? (100%)
Bigger than 1 dB? (25%)

You're already taking a 5-6 dB hit just by having it bolted to a car driving down the road. While I wouldn't say you should capriciously

throw away performance, you're already in a compromise situation.
Having less wind drag or a broader operating band might be a bigger
advantage than a dB or two.

Where you have it is about the worst
> possible
> place. :(
> I have lots of people ask me about running whips matched with tuners..
> I pretty much have a standard reply.. No! Not on my watch!
> Chortle..
> My mobile antenna is center loaded in the driving config.

And what's your operating bandwidth? Can you tune anywhere in the 40m
or 80m band? What's the efficiency of your system when you're not right
at the "sweet spot"...

The efficiency of the autotuner system is pretty constant across the band.

Now, it's possible all one needs to do is check into the nets at fixed
frequencies within a few kHz.. In which case the fixed tune system works
fine (assuming you've tuned it while actually driving...)

If you operate "mobile" (as opposed to portable, parked by the side of
the road), the autotuner takes care of the substantial change in antenna
impedance as the wind pushes it back. Or, one could mount it in the
center of the roof and guy it.. (been there, done that)

. Even higher

that's a pretty big difference.. (12 dB implies a factor of 16.. that's
like most of the Tx power being dissipated somewhere, and that sounds
like "component melting" levels)

  Have you a link to the data and test methodology?

This is the standard rebuff with "the rest of the world works differently" distractions to Walt having stated a premise, described initial conditions, taken measurements, and having shown the data supports his hypothesis. The hypothesis is dismissed through shifting initial conditions to suit an avoidance of committing an honest answer to Walt's specific and very explicit observation.

Walt, if this community were pressed for an "up or down" vote:

"Does Walt's data support the evidence of a Conjugate Match?"

then you would be out in the weeds with your only supporting vote from me (and maybe from others who would do this by email).

I doubt this will set off a stampede to the ballot box, but what few votes are stuffed in, I bet they will have the "up or down" stapled to a dissertation of "however...."

To this last, if I sinned in that regard, I used only Walt's data, his equipment references, and his citation sources. As no one else seems to tread that narrow path, much less commit beyond grandiose statements, I don't feet too bad.

In the admittedly very few looks I've had at mobile "shootout" results, there seems to be more of a correlation between vehicle size and field strength than antenna and field strength. This comes as no surprise, since the vehicle is usually a comparable or even greater part of the radiating system than the titular antenna, and its coupling to ground has a large impact on the efficiency.

For all intents and purposes, 50 and 75 ohm BNCs (both male and female) are interchangeable. They have essentially the same dimensions. You might just see that the 50 ohm male has a rather stubby point, whereas the 75 ohm version has a somewhat more steadily-tapered pin - but, unlike N-connectors, the 50 ohm male certainly doesn't cause damage to a 75 ohm female.

The thing which mainly causes the impedances to differ is the amount of PTFE dielectric present, in both sexes. On the 75 ohm version, you will normally see that it has been reduced considerably compared with the 50 ohm. Even with less dielectric, the 75 ohm version is still a bit unhappy with having too much, and this tends to lower the impedance to somewhat less than 75 ohms.

However, for all intents and purposes, you probably won't notice any significant difference between 50 and 75 ohm BNCs (mixed or not).

> =A0 Have you a link to the data and test methodology?

I summarized the data from three CA 75m mobile shootouts at:

http://www.w5dxp.com/shootout.htm

I don't recall a test methodology being published. The test receiver consisted of a ferrite loop antenna in the far field feeding a lab-grade RF voltmeter. The power incident upon the 75m mobile antenna system was assumed to be forward power minus reflected power on the coax to the antenna system, measured using two Birds. The receive results were normalized accordingly. I may have left out a detail or two.

The SG-230 plus 11.5 whip at -12 dB was equal to a 75m hamstick. I entered both the top-rated (0 dB reference) antenna and the (-12 dB) autotuner+whip on the same vehicle. When I "superposed" all of the three results, I assumed 0 dB for each top-rated antenna and let the rest fall where they might. That may or may not have been a reasonable assumption.

I suspect the SG-230 is designed to dissipate 100 watts (using large #2 material powdered-iron toroids). During one shootout episode, I forgot to attach the antenna to the mobile mount. The SG-230 faithfully tuned to close to a 1:1 match on the input - with a near-infinite SWR on the output. It was a damp foggy day and the mobile mount arced. That taught me not to mount the SG-230 unobserved in the attic. :-)

Which is why, in this case, it is well to note that the 0 dB top-rated
antenna and the -12 dB antenna were mounted on the same vehicle
(mine).

Hello Richard,

I think, most people that are willing to read will support Walt's statements on output impedance of an amplifier under matched output power (given a certain drive condition). However there are many practical circumstances where Walt's conditions are not met.

As soon as you change the drive (for example during an AM or SSB transmission), your matching is no longer guaranteed, especially when using circuits with current behavior (tetrode/pentode, common grid, etc). See my EL34 posting. Note that under practical circumstances, this is no problem.

As soon as you change the load (without changing the matching), you may run into current or voltage saturation, of course depending on phase of VSWR. As you know many people use non-tune solid-state amplifiers, so they don't have the possibility to tune/match for maximum output given certain drive.   That means, live with it, or use an external tuner where you don't tune for maximum power, but for minimum VSWR presented to the PA.

Amplifiers for constant envelope modulation use saturation to increase efficiency (and accept the loss in gain). These are deliberately used under mismatch, therefore the gain is less with respect to a non-saturating approach. You can also see this from the Pout versus Pin curve for FM transistors. I know that severak CB owners retuned (or even modified) the output stage to get 1 dB more power, but they did forget that the final transistor had dissipate 2dB more. Result: some japanese transistors became very popular (2SC1306, 1307, 1969, etc).

High efficiency circuits are the extreme case and are entering the amateur world. Active devices behave like switches, output impedance can have every value as long as it is close to the edge of the passive Smith Chart. Amplitude modulation with these topologies can only be done via supply voltage modulation. Tuning for maximum power with an external tuner will surely destroy the amplifier if no protection is present.

For me it was a surprise how this thread developed.

Best regards,

Wim

AM should be the easiest mode to analyze since it requires linear
finals.

I can tell you my experience with an about 7.5-meter carbon-fibre fishing rod, that I was intending to use as support for a 10-MHz vertical (the rod was secured to an insulated support, with some radials lying on the ground).

What is did is to run a bare copper wire along the rod, fixing it to the rod every 30cm or so using scotch tape. So, the antenna was the wire, and the rod was just a support.

After tuning the wire for perfect resonance at 10.1 MHz, I applied 1kW RF power to the antenna. The result was that the rod (and the tape) got quickly burned at most of the points where the wire was fixed to the rod (the high-voltage points).

It can be easily concluded that:

- the carbon-fire rod is indeed conductive
- its resistance is however too high for plainly using it as a radiator (i.e.without the copper wire)
- even though running low power one would probably not experience the problems I had, the antenna loss (in dB) caused to the fairly high rod resistivity would anyway be significant, independently of whether one runs low or high power.

Time to sum up where we are in this cause c�l�bre, I think.

The diameter of the centre pin in current production BNC plugs is specified as between 1.32 and 1.37mm (0.052 and 0.054 inches). This is the same for 75R connectors which are detailed in MIL-STD-348B (9Feb 2009), and 50R connectors, shown in MIL-STD-348 (20 April 1988). The earlier document does not refer to the Zo, but the drawing is clearly of a 50R socket with the extended dielectric surrounding the split pin.

Therefore - all compliant BNC connectors are mechanically compatible between 50R and 75R from April 1988 onwards. There are NO mating damage problems for current production items.

It has been suggested that prior to the introduction of IEC 169-8 in 1978, which defined interchangeability, there may have been differences in the pin diameters between 50R and 75R plugs. This will only be resolved by the actual measurement of plugs known to have been manufactured prior to 1978 - or someone producing specification documents from the time.

The definitive specification of BNC connectors would appear to be contained within IEC standard document 169-8. This does not seem to be easily available - copies must be purchased at considerable expense from the IEC. Has anyone got access to a copy of this document ?

I haven't followed this thread since it's been beaten to death so many times here before. But there's an interesting fact that might have been overlooked, and might (or might not) be relevant:

If you put a directional coupler such as a Bruene circuit at the output of a transmitter, and use its "forward" output to control the transmitter power to keep the "forward" directional coupler output constant, you'll find that the power output vs load resistance characteristic is exactly the same as if the transmitter had 50 ohm output impedance. This is assuming that the directional coupler is designed for a 50 ohm system, and that the load is purely resistive. It also assumes that any load is left in place long enough for the feedback circuit to stabilize. The effective source impedance to a very rapidly varying load (that is, one changing so fast that the ALC feedback system doesn't have time to respond) would be the open-loop output impedance which could be quite different. I haven't taken the time to analyze how it behaves with a complex load.

I stumbled across this some time ago when designing a rig using this ALC method and found it interesting. I believe many if not most modern solid-state transmitters use this ALC method.

N connectors don't have any dielectric in the mating region, so the pin diameter would have to be made smaller for a 75 ohm impedance. Maybe N connector incompatibility issues have morphed into misconceptions about BNCs. I don't think I have any 75 ohm N connectors (assuming such things exist) to look at.

That certainly explains why the diameter of the 75 ohm N pin is much,
much less than the 50 ohm. The two are certainly not mateable.

I must admit that, in the back of my mind, I'd occasionally wondered why
- and now, after over 46 years of successfully not getting them mixed up
too often (at work, it was a hanging offence to put a 50 ohm male in a
75 ohm female), all is clear! I don't know why it never dawned on me.
I'm fully familiar with the difference between the BNCs.

It looks like the rod I have used was built by winding a narrow tape on a
tapered cylindrical support (in spiral fashion).

>interaction resulting in constructive/destructive interference (what
```

>most RF engineers don't seem to understand) because, unlike optical
>physicists, have not been forced to follow the energy flow.

There is no interaction between the waves, they may be superimposed, and maybe their photons are indistinguishable, but there is no 'interaction'. interaction implies that one wave affects the other, energy is transferred or fields are affected, such things occur in non-linear media, but not in linear ones.

Hello Tom,

Well, the reason I chose to discuss only the tube amp with a pi-network filter and impedance transformer is that that arrangement is the only one I've measured, and that I'm not sufficiently acquainted with other arrangements to discuss them.

As to your question, why not use plate loads of 3000, 6000 or 1000? Because the transceivers I measured using two 6146s in parallel are Kenwood TS-830S and Heathkit HW-100. I don't remember the exact plate load with the HW-100, close to 1400 ohms, while the TS-830S was 1400 ohms. I had no control over those plate loads because the plate and grid voltages were preset, and 1400 ohms is the RL I measured at the input of the pi-network when the grid drive and the network were adjusted to deliver precisely 100w to the load 50-ohm load.

Now concerning the non-dissipative source resistance of the tube-type power amp. There are two separate resistances in the amp, the cathode-to-plate resistance, Rpd, that accounts for all the dissipation in the tube; and the output-source resistance that is non-dissipative. It is a common myth that an RF power amp cannot have an efficiency greater than 50% when conjugate matched to the load, because half the RF power is dissipated in the source resistance. This is not true, because when the amp is operating properly, resistance Rpd is less than the output source resistance, thus allowing more power delivered to the load than that dissipated in the plate-to-cathode resistance. The output source resistance is derived from the voltage-current ratio E/I that appears at the output terminals of the pi-network. A ratio, as such, cannot dissipate energy, but the load it feeds does.

Using an example from Terman's Radio Engineer's Handbook I explain this phenomenon in great detail in Chapter 19 in Reflections, and further in Chapter 19A, an addition to Chapter 19. Both are available on my web page at www.w2du.com. Chapter 19 appears in 'Read Chapters from Reflections 2', and 19A appears in 'Preview Chapter from Reflections 3'. The entire Chapter 19 appears in Reflections 3, which is now available from CQ. I invite you to review these Chapters.

Walt, W2DU

Not in years, they used to be made with different sized pins but now rely on different dielectrics for impedance.

H.

Who used to get yelled at by his boss for inserting 50 ohm males into 75 ohm females.

>
> If you put a directional coupler such as a Bruene circuit at the output of a transmitter, and use its "forward" output to control the transmitter power to keep the "forward" directional coupler output constant, you'll find that the power output vs load resistance characteristic is exactly the same as if the transmitter had 50 ohm output impedance. This is assuming that the directional coupler is designed for a 50 ohm system, and that the load is purely resistive. It also assumes that any load is left in place long enough for the feedback circuit to stabilize. The effective source impedance to a very rapidly varying load (that is, one changing so fast that the ALC feedback system doesn't have time to respond) would be the open-loop output impedance which could be quite different. I haven't taken the time to analyze how it behaves with a complex load.
>
> I stumbled across this some time ago when designing a rig using this ALC method and found it interesting. I believe many if not most modern solid-state transmitters use this ALC method.
>
> Roy Lewallen, W7EL

Hello Roy,

If you have sufficient headroom and under the conditions you mentioned, you mimic a 50 Ohms source. I think it also works for any (complex) loads (I couldn=92t find why not).

The difference between a real 50 Ohms circuit may be that the phase of the belonging EMF may change, in many amplifiers phase shift is somewhat excitation dependent, but who bothers?

I expect such scheme in combination with VSWR measurement also, as several PAs have a reverse power indicator present (the other half of a the Bruene circuit). You need the reverse power indication to avoid destroying active devices and/or intermodulation distortion due to voltage saturation.

Imagine that you have full reflection |RC| =3D 1 and it appears at your active device as RC=3D-1. You want to maintain the original forward power. Your active device has to deliver in that case double the current at zero collector/plate voltage to maintain same forward power as under matched condition. The actual power delivered to the load is zero (as the active device supplies current, but no voltage, RC=3D-1 means a short circuit). This will result in massive dissipation in the active device.

In case of RC=3D+1, it has to provide double the voltage with no current. In other circumstances you will have a significant phase shift between current and voltage resulting also in increased device dissipation and inconvenient combinations of instantaneous voltage and current. So above some value for VSWR, you may have to reduce the forward power

I had a discussion recently about the power control scheme for TETRA terminals, but we couldn't find the answer to what is happening under high VSWR (so we have measure it). It only states VSWR<2.

Best regards,

Wim

I assume you are using AOPro, since that is what you have previously stated when asked what you use for analysis. AOPro is an old version of Mininec wrapped in an optimizer with 2D and 3D result presentation. It has none of the current corrections to fix the mathematical mistakes that were made in the original Mininec. Sometimes those mistakes are relevant, sometimes not. In the case of an antenna like you describe, they probably mostly are.

If AOPro say 5 ohms + or - j something, the 5 is the real part of the feedpoint impedance. It is not the loss as you state.

The maximum wire diameters of your model seem to be impractical for use with Mininec where it is not advisable to go beyond .001 wavelengths from what I'm able to determine. Based on that assumption I get a maximum usable wire gauge for 685MHz of 25, and for 1200MHz 30. At 3000 it's a number not even on the AWG table I have -38. So to model this antenna at 3000MHz you should use 38 AWG or smaller wire for any chance of accurate results.

You also stated that it is close spaced but gave no numbers, so I can't comment on that. But I have a feeling that too may violate the limits of Mininec's calculation engine.

Be careful of what you model and how you model it. Distrust miraculous results not confirmed by other methods.

The guage was not meant to be -38, I missed the spacebar. It should
have read

"not even on the AWG table I have - 38."

I don't know. I've never seen them.

What's a hamfest? There are none here.

><http://www.rfcoaxconnectors.com>

I'll check them out.

It's less important here. It rains about 14 days a year spread over 6
months. It rained for about 10 minutes in April, has looked like, but did
not rain at all in May, and won't do it again until around November 1.

```
><http://www.santacruzelectronics.com>

I'll look at them too.
>
> I don't know what to suggest.  It sounds like getting someone in
> Europe to throw together a collection of connectors for you seems
> easier than importing them one at a time.

Actually that's a myth. While I am geographicaly closer, postage from the
US is much cheaper than Europe. The only way shipping becomes cheaper if I
were to load a container full on a ship. Then sending it from a Mediterranean
port would be cheaper.

Sending a single package from the US is cheaper and faster than anywhere
else in the world with the usual, but not always exception of elsewhere
in Israel.

A single envelope, even one containing electronic components takes a week
from a vendor to my door. A small box takes 2-3 and I have to go pick it
up at the post office, even if they are the same cost and weight.

The same with internet access, I can download files from the US at twice
the speed from the UK, and 4-5 times that from continental Europe.

Geoff.

Art you must have quite an impressive antenna lab and range. I will be
in Peoria in a couple of weeks for about 3 weeks I would like to come
over and see your setup.

Jimmie

Thanks. Interestingly enough, they have F-plugs to N jacks, (i.e. cables
with F plugs on them to connect to a radio with an N jack) but not
F plugs to PL-259(UHF) jacks. :-(

73,

Geoff.

Good day Miguel,

I do not disagree with anything you have written, but I do think it is much too early to introduce Poynting vectors and lossy conductors to the discussion.

Some of the posters to this group have basic misunderstandings of the behaviour of transmission lines and using Poynting to address these misunderstandings is like trying to use quantum mechanics to address misunderstandings of Newton=92s third law. And it will be just as unsuccessful.

The basic misunderstanding is believing that a reflected wave necessarily and always transports energy. Rather than using basic circuit theory to demonstrate that this assumption is incorrect, these posters introduce Poynting, optics and photons to reinforce their beliefs. Believing that a reflected wave necessarily transports energy then begs the question =91where does this energy go?=92. At one time it was a commonly held belief that this reflected =91energy=92 entered the transmitter and fried the final. This notion has generally disappeared, but has been replaced by faulty concepts attempting to explain how the reflected =91energy=92 is re-reflected so that is does not enter the transmitter. And all this effort is expended because of a misunderstanding of the nature of reflected =91energy=92.

Until these basic behaviours are properly understood, optics, photons and Poynting merely assist with obfuscation.

...Keith

> There are indeed negative values. These occur when the energy is
> flowing in the other direction, ...

Let's take a close look at the illusion that you are seeing and not comprehending. Observe a snapshot of the instantaneous power envelope of a traveling wave. It is a sinusoidal envelope with peak instantaneous power levels and zero instantaneous power levels. When it is traveling in the forward direction we consider that to be positive power. When it is traveling in the reverse direction, we consider that to be negative power. It is only a directional *convention* not proof that negative power exists. The only waves that can exist as waves on a transmission line are traveling waves.

Since the forward wave and reverse wave do not interact while Z0 remains constant, they have zero effect on each other and we can just simply algebraically add the two instantaneous powers to obtain the net instantaneous power. Thus, when the instantaneous power in the forward wave is a greater magnitude than the instantaneous power in the reverse wave, the net instantaneous power is positive. When the instantaneous power in the forward wave is a lesser magnitude than the instantaneous power in the reverse wave, the net instantaneous power is negative. At the point where they are equal, the net instantaneous power is zero. This is the illusion, based on net instantaneous power, that you are observing. Please note that net instantaneous power is an oxymoron. Is it net or is it instantaneous? How can it be both?

All you are observing is that sometimes the instantaneous power in the forward traveling wave is more, less, or equal to the instantaneous power in the reverse traveling wave which causes the net instantaneous Poynting vector direction to alternate. But it is all a moot point because photons cannot perform the feats of magic that you are ascribing to them. You are simply being fooled by an illusion based on the misguided algebraic addition of two separate and distinct instantaneous powers that you believe are interacting but while Z0 remains constant, they are not interacting in any way and it is impossible for the photons to change direction without a physical cause. Your mashed-potatoes version of energy doesn't even obey Maxwell's equations. Why do you think the concept can possibly be meaningful?

In "Optics", Hecht says instantaneous power is "of limited utility."
You seem to have discovered that limit, stepped over it, and stepped
in it. :-)

Note that P(t)=3DV(t)I(t) is just Pfor(t) - Pref(t) which loses information when the subtraction is performed and is not important in any meaningful way. If, as you say, loss of information is to be avoided, you should be using Pfor(t) and Pref(t) instead of net P(t).

Translation: I object to anything, including technical references and
laws of physics, that shoots my argument down. :-)

> The basic misunderstanding is believing that a reflected wave
> necessarily and always transports energy.

Please define "transport". An EM wave cannot exist without ExH energy.
If the energy associated with an EM reflected wave is equal to zero,
then the reflected wave cannot be measured and doesn't exist. But we
know that reflected waves do exist just by looking in a mirror -
causing the reflected photonic energy to be incident upon our retinas.
All of the transported energy in the reflected wave in a transmission
line is recovered during the transient state immediately following key
down. Tracking reflected energy from beginning to end result is not
difficult - optical physicists have been doing it for decades. But,
unlike your ideas, their results do not require the violation of the
laws of physics.

Basic question (at least for me) for a very poor antenna matching :
-100 w reach the antenna and 50 w are radiated.
- 50 w are "reflected", what is their fate ?
Are they definitely lost for radiation and just heat the line, the final....

JC

Hello,

If the source has a linear 50 Ohms output impedance (assuming 50 Ohm cable, no loss), all power will go back into the source. Partly in the form of heat, partly in the form of power saving. However a PA is not a 50 Ohms source, so what happens may vary.

It is very likely that some reverse power reflects back to the antenna (as the transmitter is not a source with 50 Ohms output impedance). So the reading on an instrument that measures true forward power is the sum of the real incident power plus the reflected power from the transmitter towards the antenna. Changing the load may result in a reduction or increase of total forward power. In case of a real 50 Ohms source, the forward power will not change, no matter the load.

The bad match seen from the transmitter may result in a reduction of DC input power (input current reduces), but may also result in an increase of DC input power.

So when you have reverse power reading of 50W, you cannot just say that the PA has to dissipate an extra 50W, it can be more, less and even negative. The negative case is when the input power reduces significantly and the active element has to dissipate less (with respect to the best match condition). In particular high efficiency amplifiers (where the active devices are used as switches), show strong variation in supply current versus load change. Under certain load conditions such amplifiers may show a strong decrease in efficiency resulting in high relative increase of device dissipation.

Best regards,

Wim

>   50oHm BNC socket?

The short answer is yes ! A 75 ohm BNC plug is identical to a 50 ohm
one, save that the male pin in a 75 ohm plug is smaller in diameter.
The other way round, a 50 ohm BNC plug will damage a 75 ohm BNC socket.

Yes. But you have to be careful to get the right sleeve size and
fitting them is not straightforward.

Yes !  Spit spit, yuk...  I've always had trouble with these even used
indoors.  Usually the plating fails and gives intermittent connections

It might pay you to Google "Greenpar, Amphenol, Wellshow, Synergy" and
the like.  There is a lot of good data out there.

...

What happens to the 50 joules/second of reflected energy depends upon the phasing between the source wave and the reflected wave at the source impedance. What most amateurs don't understand is there are two mechanisms that can redistribute reflected energy back toward the antenna. Those mechanisms are a re-reflection based on the physical reflection coefficient (what RF engineers understand) and wave interaction resulting in constructive/destructive interference (what most RF engineers don't seem to understand) because, unlike optical physicists, have not been forced to follow the energy flow.

If the reflected wave arrives 180 degrees out of phase with the source wave, the two waves undergo destructive interference and all of the reflected power is redistributed as constructive interference energy back toward the antenna. This is what happens at the Z0-match established at the input of an antenna tuner.

Thus your conditions of 100w forward power and 50w reflected power could be accomplished with a 50w matched source.

If the reflected wave arrives 90 degrees out of phase with the source wave, there is zero interference and the reflected power is dissipated in the source resistor (in a source with a source resistor).

If the reflected wave arrives in phase with the source wave, all of the reflected power and more than 1/2 of the source power can be dissipated in the source resistor.

Such knowledge is old hat for optical physicists who don't have the luxury of measuring voltages in light waves. They rely on a power density (irradiance) equation.

Ptot =3D P1 + P2 + 2*SQRT(P1*P2)*cos(A)

where A is the phase angle between the electric fields of two waves. The last term is called the "interference term" and that value is what most amateurs are missing in their energy analysis. If the sign of the interference term is negative, the interference is destructive. If the sign of the interference term is positive, the interference is constructive.

>However a PA is not a 50 Ohms source

Hi Wimpie,

You say this like others, with the air of "knowing." However, when I ask in response of those who "know" what the PA is NOT, what IS it?

Give me the Z value of your transmitter. Specify all initial conditions.

We have had lengthy correspondence with Walt Maxwell's very rigorously measured Kenwood TS830s that demonstrates a Z of 50 Ohms, or nearly that as is practicable (say +/- 20%); and yet your voice was missing from this discussion with evidence to the contrary.

as in the other thread, what is the mechanism of that 'interaction'
between waves? i contend there can be no 'interaction' between
forward and reflected waves if the device is linear. so in an ideal
case of a voltage or current source and ideal source resistance there
is no interaction, it is reflected by and/or absorbed in the source
depending on the impedance of the line and source. if the source is
not linear then you would have to calculate the effect of the sum of
the voltages or currents at the source to determine the effect.

The important point that I put forward is that the program is based
around Maxwells formula. In the engineering world this is factual. If
something deviates from Maxwells laws you cannot say 'don't go there'
and you cannot overthrow what the program provides and at the same
time when it is in accordance with Maxwells laws. To follow that path
is to over throw Maxwell to reinforce your own will. That is not
science.
This approach overthrows fact for success in favor of the present
approach on this group that is based on perceived probabilities that
all other competing theories are based upon.
I continue to use my program and let all the chips fall where they
may. So far, and I have a long way to go, is that skin depth minimises
as current flow
moves out of the metallic member and closer to encapsulating particles
provided by the Gaussian equation. There is no reason to put a halt to
this work until it is proven that the program deviates from Maxwells
equations and thus is fraudulent.
I and nobody else, has pointed at any specific point of my work that
specifically states that my approach is in error based on known
boundary rules and classical physics. All assaults have been based
purely on opinion, mostly in a derogatory way to preserve resistance
to change rather than the path of better understanding.

oh please put an end to it... i will tell you outright that the
program deviates from maxwell's equations! at very small or very
large extremes it deviates quite a lot! and that is of course why all
your results that you let it optimize too far are garbage, you are not
conforming with maxwell.

Sorry. Not so. This is one of the most common urban myths in RF engineering. The pin diameters of BNCs are identical between 50 and 75R. (Measure them !!)

The 50R and 75R connectors are mechanically compatible in BOTH directions. Don't take my word for it - check Amphenol's specifications: "Two distinct types of 75ohm BNCs are available, and both mate with each other and with 50ohm BNCs. "

I've been using 75R and 50R interchangeably for about thirty years, and I've had NO mating damage problems. (Mismatches don't worry me - HF only).

Note - type N and type C connectors WILL be damaged if you try to mix 75R and 50R varieties. I suspect this is the source of the BNC myth.

Also - some Chinese made BNCs are so badly made that they will damage other connectors - but this is a manufacturing tolerance issue.

Xref: g2news2.google.com rec.radio.amateur.antenna:18346

Years ago I pointed out that extending the boundary laws on the Gaussian law of statics.becoming the same as Maxwells laws pointed out the presence of particles beyond doubt. All engineers and the following chatters went along that this was false. This because there was no mention of this in any book. It took a couple of years that Richard came upon an utterance by Feyman that pointed that the path I took was not fraudulent and at last it was written in a book. So years past before Feymans writings was more widely known and this group finally changed its approach based only on what is written and not the path taken to show the presence of particles. No doubt that all opposed changes to the books and thus lost all their credability with respect to the understanding of radiation.
Now we have the attack on a computer program and alsothe total accuracy of Maxwells equationand science itself. Boundary rules are only good for a single unknown which is why Maxwell was successful. All programs on antennas use the idea of two resistances, radiation and metallic. With this they made an ASSUMPTION, and that was skin depth was a constant which allowed the removal of one unknown leaving the last unknown to equal what it takes for all factors must equal zero per Newtons laws.
The program was accepted even tho it didn't result in total facts and was disregarded by the addition of various don't go there. Fortunately they left the program as representing Maxwells equation and did not tweak it to make it what they wanted it to be.Fortunately they did not tinker with the program to make it a constant and its integrity was adhered to.

Facts
Use of Gaussian law shows the presence of particles.

Use of the above shows that skin depth of current flow is not a constant.

Use of the above produces arrays where everything is in equilibrium required by the natural laws of physics.

Use of the above provides reactiion to the gravity and rotation of the earth when subjected to boundary rules.

Use of the above shows elevation and accelleration of particles with radiation which Maxwell called displacement current because of the units presented.

Present progress shows a "wave" effect on radiation such as " packets" which reflect the tank circuit upon which radiation is based.

LIKE ALL NEW VENTURES IN SCIENCE
it is not written in the books until point by point it is accepted by its peers and I will carry on based on my own thinking until all

pieces mesh together in the same way they have upto now, so that those
with credibility outside this forum can accept my approach ,or point
out areas where there is doubts based on the basis of science

The group has shown that when classical
physics are overuled by the consideration of probabilities the result
always end in auguments mainly based around interpretations.
For myself I am following classical rules based on the idea that
Maxwells equations as well as the AO pro
program is based on fact without any added changes.
Regards
Art Unwin KB9MZ.....xg (uk)

I did check that documentation... :-(

> I've been using 75R and 50R interchangeably for about thirty years,
> and I've had NO mating damage problems. (Mismatches don't worry me -
> HF only).

I've probably used them for nearer 50 years, and had to replace damaged sockets because the bifurcated female pin had one side broken off. I am aware that some of the early plugs didn't have solidly captive pins and could move forward and cause damage. Greenpar package the plugs/sockets clearly marked 50 or 75 ohm. In all that time I've never bothered to check the specifications until now.

> Note - type N and type C connectors WILL be damaged if you try to mix
> 75R and 50R varieties. I suspect this is the source of the BNC myth.

Having taken your words and accept that I'm wrong, I can only agree that you're right and it is a myth.

Thanks for the insight.

In the past you have insisted that only average powers were relevent.
Does this mean you are ready to look at power (i.e. energy flow) in the time domain?

If so, you might appreciate
http://sites.google.com/site/keithdysart/radio6.

A rather poor translation.

You do seem to mention looking in the mirror quite frequently, as if
it
had something to do with understanding the behaviour of a
transmission
line.

My main idea is basic electricity. If the voltage or current is
always 0, so is the power. This does not violate any physics of which
I am aware.

There is no mixing as in multiplication of waveforms. Perhaps I can offer a simple analogy. Instead of two AC waveforms (forward and reflected), use a DC equivalent. Start with two DIFFERENT batteries. Connect the two negative ends together and declare that to be ground. Connect a resistor between the positive terminals. The two voltages most certainly "interact" across the resistor, resulting in the current and power being proportional to the difference between the two battery voltages. Nothing in this crude example is non-linear, so there's no need for mixing in order to get interaction.

Similarly, the coax cable acts much in the same way. The two batteries are replaced by the incident and reflected signals. At any time, or position on the transmission line, the model can be frozen and the instantaneous voltages and currents be calculated.

>if the source is
>not linear then you would have to calculate the effect of the sum of
>the voltages or currents at the source to determine the effect.

If the source (or load) is non-linear, then the waveforms seen on the transmission line will be distorted. This is unlikely because we usually don't install diodes in antennas, or build HF amplifiers with substantial non-linearities (i.e. distortion).

yes, that is my opinion as a professional software developer who has
written simulation programs that model lightning on high voltage power
lines, on towers, and in ground conductors. And also as a user of AO
from many years ago... that program is prone to optimizing into
unrealizable and obviously incorrect results, often first seen as
rapid changes in currents and gain values.   so if you really want to
continue, have fun, we all get a good laugh out of your naivety and
attempts to explain it with your own version of physics.

Ahhh. I see part of your problem. You are thinking envelopes.

You need to change your point of view to be a particular point on the
line.
At this point, there is a function that describes the voltage: V(t).
It
may or may not be a sinusoid. There is a function for the current:
I(t).
And from these can trivialy be derived a function for power:
P(t)=3DV(t)I(t).

When I clip my instantaneous voltmeter across a line and measure 0 for
all time, I can confidently say that no energy is flowing, for there
is
not. I am curious as to what you would answer?

> In "Optics", Hecht says instantaneous power is "of limited utility."
> You seem to have discovered that limit, stepped over it, and stepped
> in it. :-)

Well, Hecht may have his limitations when dealing with Optics, but
there
is no reason to expect these same limitations to apply to circuit
analysis.

it is very misleading to try to make a lumped circuit analogy out of a transmission line problem. the first step in any circuits 101 course would be to simplify the two batteries into one then solve for the single simple current across the resistor... no waves, no back and forth, no interaction between batteries, just a single current and voltage.

>
> Similarly, the coax cable acts much in the same way. =A0The two batteries are replaced by the incident and reflected signals. =A0At any time, or position on the transmission line, the model can be frozen and the instantaneous voltages and currents be calculated. =A0

they can be, but what does it prove? i want to freeze it just as the first wave gets to the load, there is no reflected wave yet, so what good is that? in order to use our common equations there are many unstated but necessary assumptions. the most restrictive of which is that we normally only solve for the sinusoidal steady state waves... this requires that a long time(in terms of the length of the line) has passed since the source was energized, that it is a single frequency pure sine wave, and that nothing is changing in time in the load or line characteristics. given all that there is no need for instantaneous values, sure they can be calculated or measured, but they are of no use in most cases.

and obviously if either one is non-linear then all the simple equations can be abandoned and a more complete analysis must be done.

...
> JC

I assume that your numbers were obtained using a directional wattmeter,
that is, forward power is 100W, 50W are reflected and by subtraction, it is computed that 50W enter the antenna, some of which is dissipated in the antenna losses and some of which is radiated.

The 100W forward and 50W reflected have no relation to actual powers but
are simply values that are constructed so that when they are subtracted
the result is the average power flowing towards the load.

From these numbers alone it is impossible to decide whether the system is operating as it should or to compute where the losses might be, or whether there are any losses at all. With an appropriate antenna tuner it is entirely possible that the transmitter is delivering its design output of 50W to the line and all of this energy is reaching the antenna and being radiated.

Thus the whole question of "where does the reflected power go?", is
rather misleading.

Looks like I should step in here, as the answer to this question is the main theme in the book Reflections--Transmission Lines and Antennas, the first edition published in 1990, the second in 2001, and the third in just this past month of May, released at Dayton.

The notion that ANY reflected power enters the source, such as an RF power amp using tubes and a pi-network, is FALSE!!! The output source resistance of these amps is non-dissipative, and totally re-reflects all reflected power from a mismatched antenna. The same is true when using an antenna tuner. When correctly adjusted the antenna tuner totally reflects all reflected power, resulting in a conjugate match at the antenna-coax mismatch, canceling all reactances in the system to zero, thus tuning the non-resonant antenna to resonance. This action if fundamental, and has been a misunderstood myth for centuries.

For proof of the above statements I invite you to read Chapter 23 of Reflections, which you can find on my web page at www.w2du.com. Click on 'Read Chapters from Reflections 2' and then click on Chapter 23.

In addition, Chapter 19 gives more insight, and the addition to Chapter 19 can be found by clicking on 'Preview Chapters from Reflections 3'. The addition shows measured data proving that the output source impedance of the RF amp is the conjugate of the complex load impedance when the pi-network is adjusted to deliver all the available power at a given level of grid drive.

Furthermore, a completely revised edition of Chapter 23 and the total
Chapter 19 appear in Reflections 3, which is now available from CQ
Magazine.

Forgot to mention that the output of the RF power amp is LINEAR, even though the input is non-linear. The reason is that the the pi-network tank circuit is not only an impedance transformer, it's an energy-storage device that isolates the output from the input. The linearity of the output is indicated by the sinusoidal shape of the output wave, and that the voltage and current are in phase when the load impedance is resistive.

Walt, W2DU

I've responded, explaining the apparent error. Basically, the models included wire loss which caused the base resistance to include some loss in addition to the radiation resistance. The models also included a loading inductor which wasn't at the base. This alters the current distribution relative to an unloaded or base loaded vertical, resulting in an a change in radiation resistance as observed at the base.

The reason that adding 25 ohms of resistance resulted in not exactly 25 ohms of increased base resistance is that part of that resistance was added at the loading coil which wasn't at the base. Impedances added anywhere except at the base will be transformed in value when observed at the base, because the current at the point where the impedance is placed is different than the current at the base. This is why, for example, a center loading coil must have more inductance than a base loading coil to effect the same change in reactance at the base.

There was nothing wrong with the models, but they don't represent the classic simplified antenna analyzed in the paper. They were easily modified to do so.

 > . . .
```

Well, if you use "basically the same parameters" you'll get "basically" the same results. But if you want exactly the same results you'll have to take more care to use exactly the same parameters.

This model contains no wire loss, and the loading coil is placed at the same segment as the source. Because it differs in these ways from the EZNEC model, you should expect to get different results, as indeed happened. Various implementations of NEC-2 should always give very nearly the same results for the same model. In virtually all cases, as this one, where they didn't seem to, it was because the models were different.

Roy Lewallen, W7EL

> Richard Clark, KB7QHC

Hello Richard,

Try the following experiment:

Measure the forward power of your PA at a convenient load. Use a directional coupler for that, not a voltage meter calibrated for power. The "SET" or "CAL" position of a VSWR meter can be used as forward power indicator.

Now make some mismatch (for example VSWR=3D2 at different phase) and read the forward power. Did it change? If so, the output impedance is no (longer) 50 Ohms. If possible, disable automatic protection to avoid changing drive level. I don't know the value for my FT7B, but I know forward power changes with load variations (as I use it as "measuring instrument" sometimes).

Virtually all power amplifiers I designed do not have a large signal output impedance of 50 ohms under significant load change. For some I measured it because of a discussion on this between colleges.

Measuring method used: change in resistive load, from voltage change you can calculate the current change, hence the output impedance. One note, except two, all where solid state.

All high efficiency designs (class E, D) that I did have output impedance far from the expected load impedance. With "far" I mean > factor 2 or < factor 0.5. I did not measure that (as it is not important in virtually all cases), but know it from the overload simulation/measurement and I did the design myself.

The reason for not being 50 Ohms (after matching) is that when you change the load, the active device will go into voltage or current saturation. This is not a hard process, so for small load variation (low VSWR values), forward power will not change much. I think this is especially true for vacuum triode PA where you have significant tube-internal feedback. For large variation (for example VSWR =3D 2.5, reflected power 18%), you will notice change in forward power for most power amplifiers.

High efficiency CW amplifiers use saturated switches (for example half, full bridge or push-pull), so behave (seen at the active device) as a voltage source. Depending on the total phase shift of the filter sections this may convert to a current source behavior (seen at the output). I had to spent much time to avoid destruction of some circuits in case of mismatch.

If you can drop me a link to the discussion of the TS830s, I would appreciate that.

Best regards,

Wim

Hello Richard,

Walt did respond and did a solid statement regarding the amplifier with matching section to obtain maximum output (so I know the conditions) This is the point where the tube/transistor is at the edge of current/voltage saturation.

At that operating point the output impedance is 50 Ohms (for small load variations). When you change the load significantly (or change drive level), current or voltage saturation will dominate, hence the output impedance is no longer 50 Ohms.   This is also the reason that PA intermodulation may occur in close spaced transmitters where some power from transmitter A enters the amplifier of transmitter B and vice versa. This also proves that there is no linear 50 Ohms output impedance.

Best regards,

Wim

> This posting is more of an update. I pulled the old W9INN down for inspection and found a crack in the PVC. It was interesting to note the imprint on the top of the center conductor (not a balun) says W2AU; however, it does not look like a W2AU on any web page. It has ground strap running from top to bottom. To make a long story short, the crack in top of the device was easily repaired using PVC cement and it passed all continuity tests. It is back in place and working FB.

That was the old or original style of the W2AU center insulator. You could get with or without a balun inside. The strap was to provide a way to ground the shield of the coax for lighting protection via the hanging eyelet. I remember them from the seventies as a common connection method.

No the size of the center conductor pin is different between 75 and 50 ohm connectors and will either make bad contact or damage the socket.

>
> 2. Are there crimp on 50 ohm BNC plugs which will work with RG6 quad shield?

I don't think so, as there are large differences in the diameter of the

2 kinds of coax, both the diameter of the center conductor and the outside diameter of the coax.

>
> 3. Are there crimp on N connectors that would fit the RG6 quad shield coax?

I've never seen any and can't think of any commercial reason that anyone would make one.

>
> 4. Are there crimp on PL-259 connectors?

Yes, I use them all the time. I like them much better than the solder on type. Most need the center pin soldered but the crimp connection to the shield is much easier and better done than when soldered

>
> Thanks in advance,
>
> Geoff.
>

It's my experience that Teflon insulated PL259's are inferior to the phenolic insulation type. The PL259 is a non constant impedance connector that gains no benefit from Teflon insulation as to impedance. The ability of Teflon to hold the center pin in placed is greatly inferior to phenolic. One of the advertised benefits of Teflon is to withstand more heat, true but by the time the connector is heated enough to hurt the phenolic, the coax your trying to install is melted way. Nickel is harder to solder to than silver but the real problem with cheap PL259s is the inside diameter of the area with holes your supposed to solder through. I've measured a few and found them to uniformly to have a too big of an inside diameter. This means there is a larger gap between the metal of the connector and the shield than should be. This gap is hard to impossible to fill with solder and makes for poor heat transfer to the braid of the shield. Finding good connectors is much harder than it used to be as most high-end equipment manufacture are not using PL259s anymore and what hams can get are largely junk I'm afraid. I've seen on ham equipment SO239, the jack half, ones that were molded metal instead of machined brass. Those are hard to thread on a plug onto and are of a soft pot metal that cracks or binds.

> At that operating point the output impedance is 50 Ohms (for small load variations). When you change the load significantly (or change drive level), current or voltage saturation will dominate, hence the output impedance is no longer 50 Ohms. =A0 This is also the reason that PA intermodulation may occur in close spaced transmitters where some power from transmitter A enters the amplifier of transmitter B and vice versa. This also proves that there is no linear 50 Ohms output impedance.
>

> Wim
> PA3DJSwww.tetech.nl

Sorry Wim, I can't agree with some of your statements in your last post. Concerning maximum output, I will agree that saturation will occur when the minimum of the peak AC plate voltage equals the peak AC grid voltage. This condition occurs when the tube is delivering its total maximum possible power. However, when the grid drive level is less than that which brings the plate-voltage minimum down to the grid-voltage level, saturation does not occur.

In addition, when the pi-network has been adjusted to deliver all the available power at some drive level less than the maximum possible power, the source resistance at the output of the pi-network will be exactly equal to its load resistance, not somewhat higher or lower. This follows from the Maximum Power Transfer Theorem. This is not speculation, but proof determined by data from many, many measurements.

Walt, W2DU

That's not necessarily true. I have some RG-59 cables with male 75 ohm BNC connectors that mate fine with 50 ohm connectors. The diameter of the 75 ohm connector center pin is the same diameter as 50 ohm connectors. The difference is that the dielectric surrounding the center pin of the 75 ohm connector is much thinner. And at the point where the pin enters the solid dielectric at the bottom, the 75 ohm pin doesn't step up in diameter.

Others have said that there are some 75 ohm BNC connectors which won't interconnect without damage. But I do know there are some that mate with no problem. 50 ohm BNC connectors and adapters are very common. I suggest you get one and compare the center pin diameter with that of your 75 ohm connector. If it's the same, the two can interconnect without damage.

I also have a lot of RG-59 cables with 50 ohm BNC connectors. That's probably more common, since 50 ohm connectors are much more common, and the connector choice won't make any practical difference in the vast majority of applications.

Please support that allegation with evidence.

What are the specified diameters of the inner conductor mating surfaces
of 75R and 50R BNC plugs ?

Include allowable manufacturing tolerances, and quote your sources.

And people have pointed out gaping holes (monstrously large errors) in
the nonsense you proclaim on a daily basis. You just refuse to

acknowledge it.

Time for the rubber room again for a while.

wrote:

>Try the following experiment:

-sigh-

Hi Wimpie,

This is not what I asked for. You said what the source was NOT, but you cannot say what the source IS.

The source is not a bipedal reptile. The source is not an elongated diphthong. The source is not the resurrection of a deity (some may argue that more than I would care to follow). The source is not....

There are many ways to say what the source is NOT, and that will never

inform us about the source. I see many draw deuces to this question
and try to convince everyone that the card is a pair of winning aces.

>Now make some mismatch (for example VSWR=2 at different phase) and
>read the forward power. Did it change? If so, the output impedance is
>no (longer) 50 Ohms.

What IS it now? If you could measure it once, you should be able to
tell us what it is this time too. I did this for years to methods set
by the National Bureau of Standards. You have drawn a deuce, not two
aces.

>Measuring method used: change in resistive load, from voltage change
>you can calculate the current change, hence the output impedance. One
>note, except two, all where solid state.

Yes, that is called a load pull, but you offer no data - another
deuce. I have done a lot of load pulls.

>All high efficiency designs (class E, D) that I did have output
>impedance far from the expected load impedance. With "far" I mean >
>factor 2 or < factor 0.5. I did not measure that (as it is not
>important in virtually all cases), but know it from the overload
>simulation/measurement and I did the design myself.

You didn't measure it, but you can state the value - interesting state
of guessing. So, what did the simulation/non-measurement give you as
a value? What IS the value? Another deuce.

>The reason for not being 50 Ohms

Reasons abound. BP is giving us reasons why the Gulf Coast shouldn't
worry. Data has proven that reasons don't work and neither does their
well. That is a Joker draw.

>High efficiency CW amplifiers

The TS830S is not such an animal. Another Deuce.

>If you can drop me a link to the discussion of the TS830s, I would
>appreciate that.

Google "Plate Resistance" in this group.

Just a minor note, but coaxial cable Arcnet connectors, using 93 ohm
RG-62a/u coax cable, also used 50 ohm BNC connectors. The terminators
were 93 ohm resistors inside 50 ohm BNC connectors:

I have no problem with your view point and it is something I am concerned about. Since I have followed this path however, every thing is meshing
and I am reporting it as I do not fear failure. But to my mind I have not hit anything to cause me to give up. On top of that nobody has raised any particular points of discussion either. Remember it took me years to convince all that extending Gauss
was OK and it provided arrays where all elements were resonant each of which can be fed. So I was right there and everybody else was in error, relying on books only and not there own education.
Now I am spreading my wings based on what the former has shown and will re evaluate again when done. At each time I will continue to share results
even if it finally shows some errors But I certainly will not stop because of intuitions from the group which up to now has been proved wrong. Nothing wrong with following the teachings of the books as followers but I am attempting to be a leader in finding truths about radiation. So far I have proved the presence of particles, realised equilibrium in every way and now I appear to be proving that skin depth is not a constant. A lot of work to do but as an engineer I knew it would take a while and on top of that I supplied it to a academic to break it down
as one always should get an independent evaluation. So far every thing that Einstein predicted has shown up in my workings such that if he had seen it there would have been no need for alternate physics proposals, not that they were without success. The final point is that it is accepted that the machinations of radiation have not yet been proven and so far following thru with classical physics has provided with interesting view points that oppose the present teachings. So I am a fool to place my engineering experience in search of the truth where others may be happy as things are.
So I am different from the rest and what is so bad about that? It is for the group to show that I am inadequate from my aproach and to this point all
that has been presented has been proven false and I still prevail. I yearn for closure which could come from those really interested in the

outcome. But at the same time in their absence I will carry on.
Future info will be on the new thread since this one is now dead and
placed in the archives.
Regards
Art

Hello Walt,

I think the problem is in the initial conditions that we use as
starting point. Your starting point is matched to maximum power output
in all cases, also under bad antenna VSWR. My starting point was a
fixed tuned amplifier, made for 50 Ohms and experiencing large
mismatch (50W reflected, 100W forward).
>
> Sorry =A0Wim, I can't agree with some of your statements in your last

> voltage level, saturation does not occur.

In that case the final tube will more or less behave like a current source (LF appraoch, there will be feedback via capacitance), so the impedance will change from the value for maximum power.

There are two saturation conditions: voltage saturation, this lowers the plate impedance, current saturation (below maximum voltage swing), this increases the plate impedance (especially for pentodes).

We start with a maximim power matched situation (so ZL =3D Zout) and don't touch the tuning.
When you now change the load (for example VSWR =3D2), you will probably have a strong voltage saturation condition or strong current saturation condition, so voltage source or current source behavior dictates, but not both. Therefore the output impedance at the plate will rise (current saturation) or decrease (voltage saturation). For triodes the effect is less then for pentodes as the transition for current saturation to voltage saturation is relatively smooth for triodes.

>
> In addition, when the pi-network has been adjusted to deliver all the available power at some drive level less than the maximum possible power, the source resistance at the output of the pi-network will be exactly equal to its load resistance, not somewhat higher or lower. This follows from the Maximum Power Transfer Theorem. This is not speculation, but proof determined by data from many, many measurements.

Fully agree with this, but is this always the case under practical circumstance?

When you change one of the paramers (drive level or VSWR, but not the matching), you will divert from the optimum setting, hence impedance will change. You can try the VSWR dependence by measuring the forward power under varying VSWR. I am sure it will change (keeping drive level and pi filter matching the same).

Most solid state amplifiers do not have the possibility of matching when you change VSWR, so with bad VSWR, you will be in the current or voltage saturating range of the active device and your output impedance will change.

Virtually all high efficient amplifiers work in voltage saturated mode and are therefore not operated at maximum available power, therefore their output impedance doens't match the expected load.

Except for CW, most SSB amplifiers run in the current saturated mode (so below maximum voltage swing), so they do not work at their maximum power point given the instantaneous drive level (or you need to modulate your supply also).

In real world the situation is more complex because of phase changes in VSWR and parasitic feedback that may change the gain of the active device (worst case spoken, you may get instability). I discovered (when I was younger) that with a class C fixed tuned amplifier, small changes in VSWR resulted in change of forward power, but significant change in DC supply current (and heatsink temperature). So what happens with the reflected power depends on many factors.

Of course, since the source impedance may be anywhere in the complex
plane, you need to change more than just the resistive part of the
load, I believe, to get an accurate picture...

>

What I've seen in similar situations is that the source impedance is likely to be strongly reactive, depending on the filter network you use to get sinusoidal output. In any event, the source impedance is likely to have a reflection coefficient magnitude that is quite close to unity. That is exactly what you should expect: there's nothing to absorb reflections. You could (theoretically at least) use feedback to make the output look like 50 ohms, but just as you say, Wim ... why?? There's really almost never any point in doing so.

...

Cheers,
Tom

Hi folks, good night (from here).

> I do not disagree with anything you have written, but I do think it
> is much too early to introduce Poynting vectors and lossy conductors
> to the discussion.

Hello Keith, Yes, I understand your comment, I introduced Poynting vector only because both, energy and power, are scalars and we can not talk about scalars having direction without get in conceptual troubles; flux of power instead, have direction because surface vector presence in its definition gives directive characteristics to power crossing an imaginary surface.
Slanted flux of electromagnetic power (Poynting) due resistive conductor simply seems to me a good example of a power flux in a TL not totally coincident with axial direction to provide a little more supporting to "directive" notion of Power Flux.
However IMHO power flux do not seems to me more complicated than power, work, voltage, potential, energy, E and H fields, etc. All of them -I believe- are not very simple stuff :>(, but they are very funny and interesting, indeed...!! :>D. What do you think?
.....
Please would you mind tell me why "sine wave" it is not a correct use of "wave" word. The only dictionary I have =3D> "Oxford advanced english dictionary of current english defines wave as: "move to and fro, up and down", I believe also in english there are word qualifiers (sine, traveling, standing, etc) who specify the precise meaning of them in diverse contexts. Am I wrong about this?.
....
Sorry by my insistence about convenience of discuss about "models".
Please let me bring a citation:
"At times, two quite differents models may serve equally well, but eventually one is usually found to prevail, not because it is right, but because it is both more convenient and more logically constructed.
After all, models are constructed for convenience in thinking and recording, not as photographic images of nature"
(From "Electromagnetic Engineering", Ronold W.P. King (PhD), page 94.
McGraw Hill.1946).
....
I studied "Principle of Conjugates Impedance Matching" in my early student days and the "mirror reflection" explained by Walter Maxwell in his article agree with my undestanding about "where the reflected waves go" because to balance magnitudes it is necessary that they found a full mismatch on its way (path?) to generator. My own limited analisis led me to the same notion even without conjugate match if I calculate Incident and reflected voltages values in a half wave TL (as my early thread example),
As I said, reading Cecil's web page quarter wave line examples led me to considerate another possible representations of the problem, in addition Owen's own ideas about it also made me consider the issue from another point of view.

Thank you very nuch.

My calculus is probably a lot rustier than yours but it would be very important for this discussion if Maxwell's equations do not work for the standing wave equation. That would essentially prove that the mashed-potatoes theory of transmission line energy is bogus.

I built one of those things in the 50's. I was feeding a resonant
1/2WL 40m with 1/2WL of TV twinlead. I could never get the reflected
bulb to go dim, no matter what I did, because 300/50 =3D an SWR of 6:1.
My reflected power was more than 1/2 of the forward power. It was only
four years later as I got close to a EE degree, that I understood why
the reflected bulb would never go dim. :-)

Hi Keith,

Each tube is dissipating 53.35W?   What a fire-eater! Each tube in an
RF application is rated for between 18W to 35 Watts maximum. However,
those maximum values are continous service, not tune up. Further, Ham

usage with long duty cycles would average the plate dissipation over the long haul to well below 50+ W.

When I review the RCA specifications for a 6146B, published Feb 1964, I find that both Walt's Plate voltage and Plate current exceed absolute maximum ratings of (depending upon service) 750V at 250mA. However, this would seem to be tolerably within generous meter inaccuracy (if I were to peg it as low as 5%). Also, the 250mA meter mark is an ad-hoc adjustment set at a condition of maximum power, not by independantly confirming the actual current. That is of little consequence to me and Walt's numbers arrived at straight from the Kenwood service manual are suitable.

However, when we return to the "dissipation," through both RF and Heat; then we are very close to the classic 50% efficiency of a matched (by Conjugate Z basis) source.

The heat from the plates satisfy every physical interpretation of a classic resistor, and an ordinary Ham transmitter exhibits what is classically called source resistance.

****

So far, all of Walt's data and extrapolations of R are right on. I have seen similar reports through alternative methods seeking the same determination that agree. However, I don't see how he then jumps the tracks to hedge R not being real and being borne by the plate of the tube.

>
> ...Keith

Keith, I measured 1400 ohms at the input of the pi-network. The output power was 100 w at 50 ohms, meaning an output voltage of 50 v and current 1.414 a. The ratio of output to input resistances of the pi-network is 28, meaning the voltage at the network input is 374.17 v. Thus, neglecting the small loss in the network, the input current to the network is 0.267 a. and the power entering the network is 100 w.

I prefer to consider the source resistance of the power amp to be at the output of the network, which, when adjusted to deliver 100 w into the 50 + j0 load, the source resistance is 50 ohms. On the other hand, if you wish to consider the source resistance at the input of the network, then it's 1400 ohms, not somewhere between 5k and 15k ohms.

Consequently, if Rp is between 5k and 15k, Rp cannot be considered the source resistance of the amp. From this info I still believe that Rp is not the source resistance of an RF power amp.

I understand that the efficiency of the amp is determined by the difference between plate power input output power, which is the power lost to dissipation in the plate that is 108 w in the example I presented. Efficiency does not include filament and grid powers.

Walt, W2DU

Richard, perhaps our disagreement on Rp is only in a misunderstanding concerning 'real'. Contrary to what you believe I said, I consider resistance Rp as real, but not as a resisTOR. And even though 'real', Rp is non-dissipative, and therefore does not dissipate any power--it only represents power that is not developed in the first place by causing a reduction of the plate voltage developed across the load current increases--so how could it be 'source' of the power delivered to a load? In the absence of Rp the output power would be greater by the amount lost by the presence of Rp.

Walt

Hi Walt,

The physical plate is in series with the load, the physical plate conducts the current in the load, the physical plate and the load both dissipate equal amounts of heat. I would presume the load is a physical resistor just as the physical plate is a resistor.

Is that load resistor dissipating power?

For your logic to be consistent, then the dummy load does not dissipate power, because it dissipates heat identical in amount and by the same physical, atomic process as steel.

If you are saying the physical plate is not a "carbon" resistor, then that is exceedingly specific and wholly original requirement that I doubt you could cite any authority demanding. It would exact that only the metal carbon qualifies and the metal steel does not when it comes to source resistance.

As I already know that there are no references available for you to cite, and this unique qualification is original to you, as your hypothesis you have to defend it with data.

Where to begin?

This might shed a little light on the discussion.

Consider a diode, forward biased by a 10 mA DC current source connected directly across it. The characteristics of this particular diode are such that the voltage is exactly 0.7 volt.

What's the resistance of the diode?

Is the diode's resistance V/I = 0.7/.01 = 70 ohms? Well, yes. The diode is dissipating power, equal to V*I = 7 mW. If we removed the diode and replaced it with a 70 ohm resistor, the voltage and current would be exactly the same as before, and the resistor would dissipate exactly as much as the diode. If the resistor's resistance is 70 ohms, then the diode's resistance is surely 70 ohms also.

Is the diode's resistance "non-dissipative"? No, it dissipates exactly as much as the equivalent resistor.

Now connect another current source across the biased diode, but make it an AC source and connect it through a capacitor. Make the AC source current 0.1 mA RMS, which is much less than the bias current of 10 mA. What AC voltage should we expect? Well, it's not 0.1 mA * 70 ohms, because 70 ohms is the DC resistance V/I, and the AC current is encountering a resistance of dV/dI, where dV/dI is the ratio of the *change* in voltage to the *change* in current. This is the dynamic, or AC resistance, and it equals the slope of the V/I curve of the diode. The AC and DC resistance are the same for a simple resistor, but not the nonlinear diode. The dynamic resistance actually changes for each instantaneous value of the AC waveform, but as long as the AC current waveform is much less than the DC bias current, the change won't be much. It turns out that the AC resistance for a diode is about 0.026/Idc where Idc is the bias current. So in our case, the AC resistance is about 0.026/0.01, or about 2.6 ohms. Therefore we'd see an AC voltage across the diode of 0.1 mA * 2.6 = 0.26 volt.

The AC voltage is in phase with the AC current through the capacitor, so the AC current source is supplying power to the diode, an amount equal to Iac * Vac = 0.1 mA * 0.26 V = 0.026 mW. What happens to this power? The answer is that the diode turns it into heat. Is the AC resistance "dissipative"? Of course it is, it's dissipating the AC power supplied by the AC current source. As before, we can replace the resistance, this time the AC resistance, with a resistor -- we'll just have to connect it through a capacitor so it doesn't see any of the DC bias. Now the equivalent diode is a 70 ohm resistor with another 2.6 ohm resistor in parallel through a capacitor. This will behave just the same as the diode, with respect to voltage, current, and power dissipation, both AC and DC, at the specified operating point.

The lengthy discussion about tube plate resistance has muddled the DC operating point (equivalent to the diode DC bias) and the plate resistance, which is the plate's AC or dynamic resistance. They're related just the same as for the diode. And just like the diode, if you were to send an AC signal to the plate of a biased tube through a capacitor, you'd find an AC voltage and current which are in phase resulting in power being delivered to the tube, and an increase in plate dissipation in the amount of that power.

Hi Walt,

If I simply look at the spec sheet for the 6146, and note that in push-pull it has a plate-to-plate Load Resistance of 3600 Ohms to 6050 Ohms (depending upon many variables); and if I simple reconfigure the two tubes from series to parallel; then the Load Resistance falls somewhere in the range of 900 Ohms to 1500 Ohms.

I am having a hard time trying to tease out how you would explain that the plates do not dissipate their half of the power when your numbers demonstrate every conventional expectation of literal and physical source resistance.

Do you have data for the peak-to-peak voltage swings at the grid and plate for the final?

I think we need to know a bit more about your application.

I have one of these pipe / cable locators, you need to have a good
idea of the route the pipework its taking and then 'sweep' the
approximate area with the end of the locator. If you don't have a
starting point it's very time consuming to cover a large area.

The avalanche beacon permits initial detection over a much wider area
which considerably speeds up a 'blind' search.

What size transmitter (physical) are you able to use, Max weight,
Battery duration, required detection radius, depth of burial etc.

UKM

Hello,

my mobile setup is composed by a 2 meter vertical whip feeded immediately
close to it by an automatic antenna tuner.

My poor knowledge of antenna systems think that the ATU, choosing the appropriate LC value, bring the entire system in a resonant condition: true or false ?

And , second question, because a friend of mine own a MFJ 269 analyzer, how i can *approximately* have an idea of the efficiency on a frequency F for my whip ?

Thanks in advance,

-.-. --.-

Missed that the expected frequency of the system is between 14 and 30 MHz, but just curious if i had any chance to work 40 meters :)

The tuner will provide an impedance match to your transceiver (50 ohms).
It won't make your antenna resonant on 20m (or any other band, other than
2m).

Hello, and that's sort of the ultimate goal. The tuner is designed to
match the antenna type(s) to the source (transmitter) and transmission
line design (characteristic) impedance.

> And , second question, because a friend of mine own a MFJ 269 analyzer, how
> i can *approximately* have an idea of the efficiency on a frequency F for my
> whip ?

The problem here is an impedance analyzer can't distinguish between
resistive losses (antenna, ground, tuner (if considered part of the

antenna)) and the radiation resistance of the antenna. To determine efficiency you'd have to make some field strength measurements (usually performed with a calibrated field strength meter) in order to determine how much of the power going into the antenna terminals is being radiated into free space. The only "approximation" would be to measure the resistive part of the antenna feedpoint impedance and then subtract from this the radiation resistance obtained from calculation. Sincerely, and 73s from N4GGO,

If you perform a frequency sweep with an antenna analyzer connected to

the tuner input and the impedance goes from R-jX ohms to 50+j0 ohms to
R+jX ohms, the purely resistive frequency meets the definition of the
system resonant frequency. Unfortunately, under those extremely
lossy conditions, "system resonance" means almost nothing.

I think "CQ" meant the whip was 2 meters long. That would be 1/4 wave
on 38 MHZ if I did the math right. This is the 8 M band? The tuner
might get it on 20 M, but 40 M will be a stretch.

Every? A classis resistor satisfies the equations
    R =3D V/I =3D deltaV/Delta/I
Given the V/I curves published for the 6146B, I see no reason to
expect
the plate resistance to satisfy these two equations.

But what exactly do you mean by 'real'?
R=3DV/I?
R=3DdeltaV/deltaI?
Heat is dissipated?

The relationship is so close, I would suggest that the Sonde is a perfect application for my needs.

Like I said previously, I want to build my own version. So we'll assume this as the target technology leaving me with the question of what antenna would be needed to perform these operations. I suppose the oscillator is just a simple crystal or perhaps even voltage controlled (adjustable). I can use a 555 for this....

I think we need to know a bit more about your application.

I have one of these pipe / cable locators, you need to have a good
idea of the route the pipework its taking and then 'sweep' the
approximate area with the end of the locator. If you don't have a
starting point it's very time consuming to cover a large area.

The avalanche beacon permits initial detection over a much wider area
which considerably speeds up a 'blind' search.

What size transmitter (physical) are you able to use, Max weight,
Battery duration, required detection radius, depth of burial etc.

Good day Miguel, you must be new here! I don't think any threads
converge to a solution. Mostly they do that singularity thing after
about the third message.

But hang in there, often much entertainment is to be had!

Miguel, do you fully realize the importance of Maxwell's equations being nonfunctional with the equation for standing waves? It means that any analysis based entirely on standing waves is probably invalid in some area of the analysis - probably including Keith Dysart's latest postings about the standing wave's zero current being meaningful in some way.

>easy, maxwell's equations don't predict standing waves! they are a
product of superposition and the simplest instrumentation used since
they were first discovered.

"Kundt's tube is an experimental acoustical apparatus invented in 1866 by
German physicist August Kundt[1][2] for the measurement of the speed of

sound in a gas or a solid rod. It is used today only for demonstrating standing waves and acoustical forces."

Heaviside wrote "Maxwell" equations" much later.

EM waves are the angular waves in the solid body. It would not be easy to instal the mirror in such body.

You do not know that EM waves were stripped away in 1864.
The Maxwell's math is used in machinery to calculate the torsion vibration.
Maxwell predicted it:

"I propose now to examine magnetic phenomena from a mecha nical point of view, and to determine what tensions in, or motions of, a medium are capable of producing the mechanical pheno mena observed. If, by the same hypothesis, we can connect the phenomena of magnetic attraction with electromagnetic phenomena and with those of induced currents, we shall have found a theory which, if not true, can only be proved to be erroneous by experiments which will greatly enlarge our knowledge of this part of physics."

The hipothesis " be proved to be erroneous by experiments" but we have the excelent math for thr solid body.

Maxwell's equations are for angular waves in the solid body.
The transmission line and ends of it (antenna) are exactly like the Kundt's
tubes. In the wires is the electron gas.

J.B. Wood wrote:

> The problem here is an impedance analyzer can't distinguish between resistive losses (antenna, ground, tuner (if considered part of the antenna)) and the radiation resistance of the antenna. To determine efficiency you'd have to make some field strength measurements (usually performed with a calibrated field strength meter) in order to determine how much of the power going into the antenna terminals is being radiated into free space. The only "approximation" would be to measure the resistive part of the antenna feedpoint impedance and then subtract from this the radiation resistance obtained from calculation. Sincerely, and 73s from N4GGO,

A good deal of, if not the majority of, the loss in a short antenna system is in the matching system components. So even if this method allowed you to get a reasonable estimate of the efficiency of the antenna itself(*), you still wouldn't know what fraction of the transmitter power is getting radiated, since you can't tell how much is lost in the tuner.

(*)My limited experience in doing careful antenna measurements leads me to be very skeptical of the ability to determine antenna efficiency even very roughly by a single impedance measurement. I think comparison of measured bandwidth to lossy model results is probably the best indicator.

The bottom line is that the impedance meter won't tell you much about the efficiency of the antenna or system. About the only practical way available to most amateurs is comparison of received signal strengths between the antenna and a known reference antenna, using a step attenuator to measure the difference.

Hi Roy,

That is a good analogy of power, non-linearity and dynamic resistance.

As for the DC operating point being muddled into the discussion, I don't think I have seen anyone raise that separately - which is perhaps what you mean.

For Walt, and all,

So, to take that part, and give this RF final stage a better view of the dynamic resistance's part in source resistance, let's consider how much power is dissipated in the plate that is strictly due to the bias and a zero input condition.

There are few typical characteristics that match Walt's data, and I have to abstract both from the TS520S schematics, service manual, and the published data for the 6146B for this. As I had to juggle these considerations to give Walt some perspective of the plate resistance being far lower than his anticipated 5 kOhm to 14 kOhm, so I must similarly reckon for the DC baseline.

By all things considered, we have a grid one bias of -60V. This exceeds the RCA published data for class AB, but not for C (which is in excess of this at -100V or more). My readings of all these variables puts the plate current for a zero input at 20-25-30mA which yields from something under 20W to something over 20W for a plate heat load. Subtract this from the 53+W Keith figured and we have a ball park 30W heat load attributable to RF. This is a back of the napkin kind of balance sheet, mind you. I say this because the drive has a cooling factor in that it drives down that zero input plate current during part of a cycle. Having said that, it is enough to simply note that there is significant heat dissipated in the plate that is attributable to the RF current that passes through it and the load.

Another fine example is a "negative resistance" device like a tunnel
diode, gas discharge tube (neon bulb), or a free burning arc.

Obviously, the arc dissipates power, but the V/I slope is negative.

presuming you mean your whip is 2 meters long (not tuned for the 2 meter band, and only 50 cm long)

On 40m? Maybe, maybe not. people have used a light bulb as an antenna.

It will almost certainly be inefficient. Here's a short description (filled with technical detail errors, which will no doubt provoke a long discussion)..

All antennas have a property called "radiation resistance" (smaller antennas have smaller radiation resistances)
All antennas also have resistive losses.
There are also losses "after the wave has left the antenna" (e.g. ground reflections, etc. why salt water marshes are prized for vertical pol).
The latter are not considered here.

To a first order (back, all you nit pickers.. first order), the power from the transmitter gets distributed between the radiation resistance and the loss resistance. So, the "efficiency" can be thought of as that fraction of power that winds up in the radiation resistance, as opposed to in the loss resistance.

Important here: if the radiation resistance is low, that doesn't mean poor efficiency: as long as you keep the resistive losses low too.. which can be a challenge (assuming you're not carrying a vat of liquid helium, for instance).

Part of the problem is that the resistive losses aren't just in the antenna, but also in any substance which is immersed in the antenna's electric and magnetic fields (like the steel of your car, and the not particularly good conductivity, but not a perfect insulator either, soil under the car).

And, then, there are losses in how you get from Tx to Antenna. If your antenna presents an impedance that is not what the transmitter is providing, you've got to transform it somehow, typically using Ls and Cs, etc. (in your autotuner). Those components also have some amount of loss, although I'll bet it's less than 10% in most situations (otherwise, the tuner/matching network would melt, and they don't)

Moral of story..
radiation resistance doesn't drop much from a full size antenna until you get around 1/10th wavelength, then it starts to drop real fast (as length squared)

For a dipole:
L/lambda = 1/2, R= 73 ohms
L/lambda = 1/5, R = 8
1/10, 2

1/20, 0.5
1/50, 0.08
1/100, 0.02

On 40m, your 2m long whip is like a 4m long dipole: 1/10 (in the above table) for 2 ohms. Since it's a monopole, it's actually half.. 1 ohm..

That's pretty low..

A bunch of people have measured loss resistances for typical mobile installations and they get numbers in the 10-20 ohms range, so you're looking at an efficiency of about 10% of what you'd get with a full sized 10m tall vertical.
(this isn't far off the "mobile antenna is a 6dB hit" empirical observation)

I'm assuming here that somehow you'll be able to match the 50 ohms in the feed line to the 10-20 ohms with a lot of reactance at the feedpoint without too much loss (a reasonable assumption)

Richard, you ask me where to begin. Well, I begin with Terman, where I quote him in Chapter 19, Sec 19.3, in Reflections 2. Since attachments are prohibited in this forum I'm going to try to copy Sec 19.3 here, which explains in detail why plate resistance Rpd is dissipative, while Rp is non-dissipative--it explains the difference between the two. In addition, I don't believe the diode is a correct model for describing the operation of a Class B or C amplifier. Now the quote:

Sec 19.3 Analysis of the Class C Amplifier

The following discussion of the Class C amplifier, which reveals why the portion of the source resistance related to the characteristics of the load line is non-dissipative, is based on statements appearing in Terman=92s Radio Engineers Handbook, 1943 ed., Page 445, and on Terman=92s example of Class C amplifier design data appearing on Page 449. Because the arguments presented in Terman=92s statements are vital to understanding the concept under discussion, I quote them here for convenience: (Parentheses and emphasis mine)

1. The average of the pulses of current flowing to an electrode represents the direct current drawn by that electrode.
2. The power input to the plate electrode of the tube at any instant is the product of plate-supply voltage and instantaneous plate current.
3. The corresponding power (Pd) lost at the plate is the product of instantaneous plate-cathode voltage and instantaneous plate current.
4. The difference between the two quantities obtained from items 2 and 3 represents the useful output at the moment.
5. The average input, output, and loss are obtained by averaging the instantaneous powers.
6. The efficiency is the ratio of average output to average

input and is commonly of the order of 60 to 80 percent.

7. The efficiency is high in a Class C amplifier because current is permitted to flow only when most of the plate-supply voltage is used as voltage drop across the tuned load circuit RL, and only a small fraction is wasted as voltage drop (across Rpd) at the plate electrode of the tube.

Based on these statements the discussion and the data in Terman=92s example that follow explain why the amplifier can deliver power with efficiencies greater than 50 percent while conjugately matched to its load, a condition that is widely disputed because of the incorrect assumptions concerning Class B and C amplifier operation as noted above. The terminology and data in the example are Terman=92s, but I have added one calculation to Terman=92s data to emphasize a parameter that is vital to understanding how a conjugate match can exist when the efficiency is greater than 50 percent. That parameter is dissipative plate resistance Rpd. (As stated earlier, dissipative resistance Rpd should not be confused with non-dissipative plate resistance Rp of amplifiers operating in Class A, derived from the expression Rp =3D delta Ep/delta Ip.)

It is evident from Terman that the power supplied to the amplifier by the DC power supply goes to only two places, the RF power delivered to load resistance RL at the input of the pi-network, and the power dissipated as heat in dissipative plate resistance Rpd (again, not plate resistance Rp, which is totally irrelevant to obtaining a conjugate match at the output of Class B and C amplifiers). In other words, the output power equals the DC input power minus the power dissipated in resistance Rpd. We will now show why this two-way division of power occurs. First we calculate the value of Rpd from Terman=92s data, as seen in line (9) in the example below. It is evident that when the DC input power minus the power dissipated in Rpd equals the power delivered to resistance RL at the input of the pi-network, there can be no significant dissipative resistance in the amplifier other than Rpd. The antenna effect from the tank circuit is so insignificant that dissipation due to radiation can be disregarded. If there were any significant dissipative resistance in addition to Rpd, the power delivered to the load plus the power dissipated in Rpd would be less than the DC input power, due to the power that would be dissipated in the additional resistance. This is an impossibility, confirmed by the data in Terman=92s example, which is in accordance with the Law of Conservation of Energy. Therefore, we shall observe that the example confirms the total power taken from the power supply goes only to 1) the RF power delivered to the load RL, and 2) to the power dissipated as heat in Rpd, thus, proving there is no significant dissipative resistance in the Class C amplifier other than Rpd.

Data from Terman=92s example on Page 449 of Radio Engineers Handbook:

(1) Eb =3D DC Source Voltage =3D 1000 v.
(2) Emin =3D Eb - EL =3D 1000 - 850 =3D 150 v. [See Terman, Figs 76(a) & 76(b)]
(3) Idc =3D DC Plate Current =3D 75.l ma. 0.0751a.

(4) EL =3D Eb - Emin =3D 1000 -150 =3D 850 v. =3D Peak Fundamental AC Plate Voltage
(5) I1 =3D Peak Fundamental AC Plate Current =3D 132.7 ma. 0.1327 a.
(6) Pin =3D Eb x Idc =3D DC lnput Power =3D l000 x 0.0751 =3D 75.l w.
(7) Pout (Eb - Emin)/2 =3D ELI1/2 =3D Output Power Delivered to RL =3D [(1000 -150) x 0.1327]/2 =3D 56.4 w.
(8) Pd =3D Pin - Pout =3D Power Dissipated in Dissipative Plate Resistance Rpd =3D 18.7 w,
(9) Rpd =3D 18.7W/0.0751^2 =3D Dissipative Plate Resistance Rpd =3D 3315.6 ohms
(10) RL =3D (Eb - Emin)/I1 =3D EL/I1 =3D Load Resistance =3D 850/0.137 =3D = 6405 Ohms (6400 in Terman)
(11) Plate Efficiency =3D Pout x 100/Pin =3D 56.4 x 100/75.1 =3D 75.1%

Note that Terman doesn't even mention non-dissipative plate resistance Rp, and therefore it cannot be considered the source resistance.

Note also in line (10) that RL is determined simply by the ratio of the fundamental RF AC voltage EL divided by the fundamental RF AC current I1, and therefore does not involve dissipation of any power. Thus RL is a non-dissipative resistance. (For more on non-dissipative resistance see Appendix 10.)

Referring to the data in the example, observe again from line (10) that load resistance RL at the input of the pi-network tank circuit is determined by the ratio EL/I1. This is the Terman equation which, prior to the more-precise Chaffee Fourier Analysis, was used universally to determine the approximate value of the optimum load resistance RL. (When the Chaffee Analysis is used to determine RL. from a selected load line the value of plate current I1 is more precise than that obtained when using Terman=92s equation, consequently requiring fewer empirical adjustments of the amplifier=92s parameters to obtain the optimum value of RL.) Load resistance RL is proportional to the slope of the operating load line that allows all of the available integrated energy contained in the plate-current pulses to be transferred into the pi-network tank circuit. (For additional information concerning the load line see Sec 19.3a below.) Therefore, the pi-network must be designed to provide the equivalent optimum resistance RL looking into the input for whatever load terminates the output. The current pulses flowing into the network deliver bursts of electrical energy to the network periodically, in the same manner as the spring-loaded escapement mechanism in the pendulum clock delivers mechanical energy periodically to the swing of the pendulum. In a similar manner, after each plate current pulse enters the pi-network tank curcuit, the flywheel effect of the resonant tank circuit stores the electromagnetic energy delivered by the current pulse, and thus maintains a continuous sinusoidal flow of current throughout the tank, in the same manner as the pendulum swings continuously and periodically after each thrust from the escapement mechanism. The continuous swing of the pendulum results from the inertia of the weight at the end of the pendulum, due to the energy stored in the weight. The path inscribed by the motion of the pendulum is a sine wave, the same as at the output of the amplifier. We will continue the discussion of the flywheel effect in the tank circuit with a more in-depth examination later.

Let us now consider the dissipative plate resistance Rpd, which provides the evidence that the DC input power to the Class C amplifier goes only to the load RL and to dissipation as heat in Rpd (Again, not Rp.) With this evidence we will show how a conjugate match can exist at the output of the pi-network with efficiencies greater than 50 percent. In accordance with the Conjugate Matching Theorem and the Maximum Power-transfer Theorem, it is well understood that a conjugate match exists whenever all available power from a linear source is being delivered to the load. Further, by definition, RL is the load resistance at the tank input determined by the characteristics of the load line that permits delivery of all the available power from the source into the tank. This is why RL is called the optimum load resistance. Thus, from the data in Terman=92s example, which shows that after accounting for the power dissipated in Rpd, all the power remaining is the available power, which is delivered to RL and thence to the load at the output of the pi-network. Therefore, because all available deliverable power is being delivered to the load, we have a conjugate match by definition. In the following Sec 4 we will show how efficiencies greater than 50 percent are achieved in Class C amplifiers operating into the conjugate match.

Thanks to all

Hey boys! (Cecil, David, Michael, et al) It is very funny and entertaining, I enjoy your postingss mostly in "read only" mode because translate not simple mine ones still being a struggle for me :-)
....
Cecil, I never studied standing waves with Maxwell equations (except in usual examples of cavity resonators cases learning classes), I studied only classic electric differential solution to the telegraper's equations.

Hi Keith: We tend to think of energy as a "tangible and real" easely intuited thing "out there" (as a water or horses) but we must not forget energy is a really elusive CONCEPT devised to explain changes in physical systems. Familiarity tend us to fetishize concepts, then we easily can get caught in troubles type =3D> "Where velocity goes when the car smash?" :-D :-D. We must be carefully with forces, powers, velocities, etc. in this sense...
Note how Terman prudenty deals with differential solution of Telegrapher's equations: "This combinatiosn of voltage and current can be INTERPRETED as a wave train traveling toward receiver" (1) (capitalized letters by me).

The very term "standing waves" leads to endless Ham controversies about concept of "wave" word in our context.(wave as "a disturb that propagates" and wave as pattern-figure-graphics-representation of interference pattern of voltage/current measured along the TL). This "wave pattern" (is it correct to write "wavy" pattern?) do not carry any energy from one place to another on the TL it is not a "wave" in the other sense (transport phenomena). What do you think?

Can I use any wire or does it have to be a certain kind?

I've asked about coiling wire but I didn't get any positive feedback.
However, it wasn't described as impossible.

You report Pout, but we cannot use this formula for lack of data.
Pout = 100W

> (8) Pd = Pin - Pout = Power Dissipated in Dissipative Plate Resistance Rpd = 18.7 w,

From your report of Pin and Pout:
Pd = 108W

> (9) Rpd = 18.7W/0.0751^2 = Dissipative Plate Resistance Rpd = 3315.6 ohms

From what is reported by you:
Rpd = 108W/(.260mA)�
Rpd = 1597 Ohms

> (10) RL = (Eb - Emin)/I1 = EL/I1 = Load Resistance = 850/0.137 = 6405 Ohms (6400 in Terman)

You do not report Emin but you report Load Resistance
RL = 50 Ohms

> (11) Plate Efficiency = Pout x 100/Pin = 56.4 x 100/75.1 = 75.1%

Plate Efficiency = 48%

By all reckoning according to your reference from Terman, using what you report, it appears that you have exhibited a Conjugate basis Z match as you claim, and that the plate Rpd by the same reckoning is the same as we formerly arrived at Rp. It would appear that over the course of some dozen years between publications that Terman simplified the term Rpd to Rp which, according to you, is not found in your volume, and as such this migration of terms seems logical by the numbers agreeing in both volumes for different labels. Inasmuch as Rpd does not appear in Terman's later work, nor in any of the Tube specifications since that era, Rpd appears to be an orphan.

You report your own Rp (now Rpd) or its equivalent by resistor substitution (a valid determination) to be on order of 1400 Ohms. This conforms closely to the value found above, and the data reported by RCA for Rp in a design of similar characteristics. The range of possible values taken from RCA: 900 Ohms to 1500 Ohms.

Taking your low, the high from my range, and the higher computed through your supplied data using Terman's formula, the average is 1500 Ohms with a variation of roughly 6% which is about the limits of superlative accuracy for conventional bench equipment. What this means is that all three values are identical on the basis of accumulation of error.

Having said that, this is not the end of analysis. However, at the first pass your data has demonstrated that the Plate serves as a real resistor dissipating half of the available power being supplied to a load that is conjugately matched.

The only difference is that you state as much, but dismiss the plate dissipation as being a real resistor. Perhaps I mis-state you. If not, I take issue with that and ask once again, as this perception is unique to your hypothesis, do you have data that differentiates the resistance of steel absorbing and dissipating the impact of the electron stream as being different from carbon absorbing and dissipating the impact of the electron stream?

Would it serve to replace the steel plate with a graphite one like the 845 (similar to the GM-70)? When I review the spec sheets for this tube, it reports an Rp of 1700 Ohms - hardly remarkable at 100 more Ohms than the computation above. Of course, there are compounding application differences, but still, graphite plates or steel don't seem to force a new conclusion. Materials don't seem to be an issue.

Certainly the mechanisms of resistance differ in the kinetics of speed, but not in the product of heat. To my knowledge, no authority bases the concept of resistance upon the speed of the electron, but rather in the kinetics of its collision.

Richard, I'm totally shocked by what I've read above. I can't believe
it! I can't believe you've distorted what I've written in my last post
above to the extent that I can't possibly clarify or correct it--it's
more than just misunderstanding. In addition, it's totally misleading
to other readers of this thread, and makes me appear as a moron and an
idiot.

Sorry, Richard, I'm through with this thread. There's nothing I can do
now to fix the situation.

Walt, W2DU

I checked this out one time and my memory is a bit hazy. Using my
computer program which ofcourse could have a glitch in it, I found
that the gain hit a max at the very low resistance value and then
backed off as the resistance became close to zero. This blip occurred
during the last fraction of an ohm
just prior to closure of supplying gain figures.
At the time I put this down as the point where the skin depth
penetration was minimal and thus we had reached a point where the
applied current was totally to provide gain after which it dropped
dramatically. I looked at this as a progression for the current flow
in the surface of the element where it progressed to the surface and
the flow
progressed above the surface but below the particle encapsulation.
Further progression created losses and thus the gain blip dropped.
Resistance never dropped to zero thus ohms law
was not declared invalid. If somebody could duplicate the above via
another program it may prove interesting. Keep- dropping the applied
frequency until you reach about 0.7 ohms and then start recording.

It's possible..  But feeding a whip with a tuner usually does not
make
for an efficient mobile antenna. Not only are many/most tuners more
lossy than say using a loading coil on the whip, but current
distribution
suffers. Maximum current will be at the tuner which is not desirable.
The location of the loading coil has a large effect on the current
distribution
and efficiency of the antenna. Where you have it is about the worst
possible
place.  :(
I have lots of people ask me about running whips matched with tuners..
I pretty much have a standard reply..  No!  Not on my watch!
Chortle..
My mobile antenna is center loaded in the driving config.. Even higher
if
I add the 3 foot lower mast, but that's only when parked. In the
parked config,
my loading coil is 8 ft above the base of the whip. "14 ft tall whip"
And yes, you can tell a pretty good difference from the normal driving
config,
with the coil at 5 ft above the base.  "11 foot tall whip"

```

...

> The lengthy discussion about tube plate resistance has muddled the DC operating point (equivalent to the diode DC bias) and the plate resistance, which is the plate's AC or dynamic resistance. They're related just the same as for the diode. And just like the diode, if you were to send an AC signal to the plate of a biased tube through a capacitor, you'd find an AC voltage and current which are in phase resulting in power being delivered to the tube, and an increase in plate dissipation in the amount of that power.
>
> Roy Lewallen, W7EL

I'm happy to see that Roy posted this clarification about dynamic versus static resistance. I haven't read all the posts here, but those others that I have seemed to completely skirt the issue of the meaning of "plate resistance."

Further to Roy's posting, though, you must realize that a device with more than two terminals is complicated by the fact that you need to specify that the dynamic resistance is measured with other terminals held constant. So, for example, plate resistance of a tube is normally defined as the partial derivative of plate voltage with respect to plate current, with the grid-to-cathode voltage held constant, and of course at some particular plate voltage (and corresponding current). For a tetrode, the screen-to-cathode voltage must also be constant.

The reason for this is that you will get completely different answers if you don't hold the voltage of the grids constant with respect to the cathode. For example, if you set up a circuit with a tube with the grid grounded, and an appropriate resistor between the cathode and ground (not bypassed), to establish a desired bias point, then a change in plate current will be accompanied by an essentially identical change in cathode current, and a corresponding change in drop across the cathode resistor, which represents a change in grid-to-cathode voltage. Measuring dV/dI at the plate in such a circuit will yield a much higher resistance than if the grid-to-cathode voltage is kept constant. It is, in fact, a good way to make a constant current source.

There is no particular relationship that must be maintained between the load resistance you present to an amplifier element -- a tube or a bipolar transistor or a FET -- and the plate/collector/drain (dynamic) resistance of the device. For example, it's common to operate a push-pull pair of 6146's in audio service with a load around 5000 ohms (plate to plate) at 500V plate supply voltage, 185V screen voltage, and perhaps 30mA plate current. That's effectively 2500 ohms to each plate of the pair. But at that operating point, the plate resistance of a 6146 is around 600V/30mA, or 20k ohms (roughly, from plate characteristic curves in my old RCA transmitting tubes manual). On the other hand, a triode will have a much lower plate resistance, likely similar to the load resistance--but again, not really related to it.

Another rather interesting thing happens, though, when you connect an RF load through a tank circuit such as a PI network. It's quite possible for a pi network to transform a 50 ohm RF load so it presents a reasonable (say) 4k ohm RF load to the plate of a tube like a 6146. But that same pi network will in turn transform the plate resistance--or rather, the net impedance of the tube in its particular circuit configuration (grounded grid or grounded cathode, and invariable some amount of feedback whether you wanted it or not), along with the DC feed (RF choke) in parallel, to quite possibly an impedance not very close to 50 ohms, and likely rather reactive. I can, without much difficulty, design a PI network that will yield a source resistance at the output connector that's a lot less than 50 ohms, using a tetrode amplifier tube, while giving a very decent transformation of a 50 ohm load to a desired load at the plate of the tube.

And as if that weren't enough, I can modify the output impedance further by application of feedback; this is more commonly done at audio frequencies, where amplifiers designed to drive loads like 4 ohms an 8 ohms have output impedances in the area of a small fraction of an ohm. But it's also done with RF amplifiers, often for reasons unrelated to the output impedance, but also to control the output impedance so that it IS very close to 50 ohms (for example in instrumentation, where it may be important).

Cheers,
Tom

Indeed, Keith...nor is it much use, by itself, for computing the source impedance seen looking back into amplifier's output RF connector, at the output end of the network that transforms a (50 ohm, or whatever) load to the impedance seen by the tubes driving that load.

If the tube is operated with cathode (RF) grounded and driven with a stiff voltage source, the impedance looking back into the plate side will be the plate resistance, shunted by stray and tube capacitances; but put a bit of unbypassed cathode resistance in there and the resistive part seen at the plate will be higher, possibly quite a bit higher. Use a triode instead of a pentode, and the plate resistance will be much lower, even though the optimal load presented to the plate may well be quite similar to the optimal load presented to a tetrode. Run the tube grounded-grid and the impedance seen looking back into the plate will be much higher than if it's run grounded-cathode.

I think it helps to understand that the "optimal" load presented to the tube depends on what you want to accomplish: you want a reasonable amount of RF output power with reasonable efficiency and tube operating conditions that will yield good tube life (normally, in our circles). If it's supposed to be a linear amplifier, you want to keep (intermodulation) distortion products below some level. All that has very little to do with the impedance seen by the load looking back into the tube.

Of course, essentially the same situations exist with transistors and FETs as with tubes.

Cheers,
Tom

Thanks to all. Now is a clear statement that my problem is measuring the "inefficiency" of the entire system :)

Only to mention that due to a sort of "quiet life way" with the neighbors, my home setup is a ATU CG-3000 feeding 9,5 meters height monopole with about 40 random lenght radials (from 5 to 20 meters of lenght) and electrically connectet to 200 square meters of chicken fence, with real chickens inside :) perform quite well on 80, from 40 to 12 meters is probably the best antenna i ever had compared to old dipoles, in 10 maybe it is too close to 1 WL... but work almost all , even in furiouses pile ups.

Now that I annoyed with this info, the conclusion of the OP or the third question if you want: how it is possible that mobile setups with the "motorized" antennas can have a minimum of efficiency in 40 meters ?? What the difference from a variabile motoryzed L and an ATU at the feed point ?? Or i miss something important about the 2 feeding methods ??

TIA,
-.-. --.-

well, i dug out mathcad that will do the ugly symbolic differentiation for me. the standing wave equation can not satisfy the wave equation derived from maxwell's equations as shown in either 'Fields and Waves in Communications Electronics' section 1.14 or 'Classical Electrodynamics' section 6.4. Both of them come down to the requirement that the second derivative wrt space be proportional to the second derivative wrt time. The proportionality constant is the velocity squared. In order to satisfy this the equation must be a function of the form F(t-x/v), the normal representation is the complex exponential which can be presented in a form like sin(t)cos(x/v)-cos(t)sin(x/v) the simpler standing wave equation sin(kx)sin(wt) has the wrong relationship between space and time and therefor can't be a solution to the wave equation. When i work through the second derivatives and collect terms it results in something like Asin(kx)sin(wt)(k^2-w^2) which makes no sense, even in a dimensional analysis the units don't work.

The easiest explanation though is still the intuitive one, the solution of the wave equation derived from maxwell's equations results in the proportionality constant of 1/c^2 which requires the speed of the wave to be c in the medium where it is evaluated, there is no way to get that from the standing wave equation since it is obviously stationary wrt space.

Thanks David, that's good news. It apparently means that the arguments based on energy not crossing a current node boundary in a standing wave are invalid - since that singular condition violates the boundary conditions for Maxwell's equations. So does the "standing wave energy standing still" argument. Not only does the photonic nature of EM waves require them to travel at the speed of light in the medium, but so does Maxwell's equations.

Such knowledge also has ramifications for the technique of using the current on a standing wave antenna to try to predict the delay through a loading coil. If a Maxwell equation analysis of such a condition yields bogus results, how can simple current phase measurements be trusted? If the component traveling waves associated with a loading coil were used in order to obtain a valid Maxwell equation analysis, I wonder what would be the predicted delay through the coil?

> into free space.

The radiation resistance present at the base of an electrically short, linear, monopole (whip) antenna of various ODs can be calculated rather accurately using equations found in various antenna engineering textbooks

So if the base current entering the whip itself can be measured, and whether or not a loading coil was used at the base to resonate* the antenna system, and regardless of the loss in the r-f ground used by the whip -- then for practical purposes the power radiated by the antenna system will be the product of the square of that base current, and the radiation resistance of the whip.

* However "resonated" antenna systems using a short whip do not have the same radiation performance as those using a naturally resonant 1/4-wave monopole. Resonance just means that the capacitive reactance at the feedpoint of the short whip has been exactly offset by the inductive reactance of a loading coil, which can allow for the most efficient power transfer into the radiator.

However the radiation resistance of the whip is not changed by this process -- it is still very low compared to a naturally resonant 1/4-wave monopole. Therefore the radiation efficiency of such a short, loaded, whip antenna system cannot approach that of a naturally resonant 1/4-wave monopole unless the losses in the loading coil and r-f ground are nearly zero.

Loading coils do not replace the "missing degrees" of an electrically short radiator, as far as its radiation resistance is concerned. The radiation resistance of a whip depends only on the electrical length/OD of the whip, itself.

Most screwdrivers and bugcatchers are more center-loaded than base
loaded. The section of the antenna that supplies a good part of the
radiation is the straight section between the feedpoint and the bottom
of the loading coil. An ATU driven whip doesn't possess that high-
efficiency, high-current section. The highest current sections in an
ATU system are inside the ATU - not good for radiation. Everything
else being equal, a center-loaded antenna will beat a base-loaded
antenna by ~3-5 dB according to mobile shootout results. The radiation
resistance for a center-loaded 75m mobile antenna is approximately
double that for a base-loaded 75m mobile antenna, i.e. close to double
the efficiency.

According to 75m mobile shootout results, an ATU driven whip is ~8 dB
down from a base-loaded bugcatcher because the bugcatcher coil
radiates and an ATU is usually shielded and often uses powdered iron
toroids for the coils.

This is true only if you don't confuse the idealized textbook models
with real antennas. But most of us are unfortunately stuck with using
the latter. In general, the impedance you calculate with the idealized
models doesn't match that of real world antennas. It works pretty well
for AM broadcast installations, where the length and large number of

radials make the impedance relatively independent of ground characteristics. But this doesn't describe the typical amateur monopole antenna, either ground or mobile mounted.

An approximation to input resistance can be made by adjusting for an abbreviated radial system, but this gets increasingly unreliable as the number of radials decreases. The best readily available modeling program allowing the inclusion of a buried ground system, which uses the same well-established equations as textbooks, is NEC-4. It, however, suffers from a serious shortcoming in doing this calculation -- it assumes that the ground is homogeneous to an infinite depth. Real ground is typically stratified, and skin depth at HF is as much as several tens of feet, so the representation of real ground is very poor. There are many cases where a single "equivalent" value of homogeneous ground doesn't exist which gives the same results as actual measurement. I've made very careful measurements of a simple vertical monopole with various numbers of buried radials whose impedance couldn't be matched with NEC-4 using any ground parameters, and I believe this to be a common occurrence. In no case would I depend on a computer model, let alone an even more simplified textbook model, to predict the resistance of a real monopole having an abbreviated ground system with enough accuracy to reasonably estimate the efficiency.

As a side note, Brown, Lewis, and Epstein's sparse radial results can be matched reasonably well with NEC-4, but it does require a fair amount of ground constant adjustment for various numbers and lengths of radials.

Mobile mounted whip antennas fare even worse relative to simple textbook models. I don't have any experience with comparison of computer models with actual measurement. Those results should depend on the care with which the model is constructed and the amount of influence the ground has on the impedance.

There was a calculation error in my recent posting. Thanks to Tom, K7ITM
for spotting it and letting me know. It doesn't affect the conclusions.

The AC voltage across the diode is 0.26 mV, not 0.26 V.

> The AC voltage is in phase with the AC current through the capacitor, so
> the AC current source is supplying power to the diode, an amount equal

> to Iac * Vac = 0.1 mA * 0.26 V = 0.026 mW. . .

The power supplied by the AC current source to the diode is 0.1 mA * 0.26 mV = 0.026 uW = 26 nW, not 0.026 mW. This is, of course, also Iac^2 * Rac = (0.1 mA)^2 * 2.6.

Yes, understand *perfectly*. My energy go somewhere, and this "somewhere" is heating some toroid into a shield case or radiate on the air. Conservation law.

Center load i think mean also lower ground loss, IIRC.

And as i understand, a RX shootout of the mobile whip compared with my full size 1/4 wl vertical antenna with the same transceiver, to have a suitable relative dB comparison, can give the best test measure i can do with my actual equipement.

Thanks Cecil an other posters, other suggestions or links to learn more are
very appreciated.

For the sake of discussion, below are two pastes from the same NEC model using the demo version of EZNEC v. 5.0 -- which rather well support my earlier post that the radiation resistance (NOT the impedance) of an electrically short monopole is a function of its electrical length, and not the loss resistance of the r-f ground and/or the loading coil.

CASE 1 =3D Zero loss resistance and reactance in the r-f ground, and zero loss resistance in the loading coil:

```
                    EZNEC Demo ver. 5.0

1650 kHz  3 meter monopole                   6/4/2010     10:50:57 AM

         --------------- SOURCE DATA ---------------

Frequency =3D 1.65 MHz

Source 1      Voltage =3D 0.08578 V at 35.09 deg.
              Current =3D 0.4986 A at 0.0 deg.
              Impedance =3D 0.1408 + J 0.09888 ohms
              Power =3D 0.035 watts
              SWR (50 ohm system) > 100  (25.17 ohm system) > 100
```

CASE 2 =3D Same model as above, except with a total of 25 ohms loss in a loading coil and r-f ground, and no reactance in the r-f ground:

```
                      EZNEC Demo ver. 5.0

1650 kHz  3 meter monopole                   6/4/2010     10:49:40 AM

         --------------- SOURCE DATA ---------------

Frequency =3D 1.65 MHz

Source 1      Voltage =3D 0.9386 V at 0.22 deg.
              Current =3D 0.03729 A at 0.0 deg.
              Impedance =3D 25.17 + J 0.09579 ohms
              Power =3D 0.035 watts
              SWR (50 ohm system) =3D  1.987  (25.17 ohm system) =3D
1.004
```

EZNEC calculated the radiation resistances of these two cases to be 0.14 ohms and 0.17 ohms, respectively -- fairly close, but not exact. Perhaps Roy could comment on the reason why their agreement using NEC/EZNEC is not better.

Those wanting a good resource for the measured results for monopoles of less than 1/8 electrical wavelength might try to locate the paper by Carl E. Smith and Earl M. Johnson titled PERFORMANCE OF SHORT ANTENNAS, published in the October, 1947 edition of the Proceedings of the I.R.E.

The equation for the radiation resistance of short antennas given in that paper is independent of the resistive losses in any loading coil or r-f ground system.

This posting is more of an update. I pulled the old W9INN down for inspection and found a crack in the PVC. It was interesting to note the imprint on the top of the center conductor (not a balun) says W2AU; however, it does not look like a W2AU on any web page. It has ground strap running from top to bottom. To make a long story short, the crack in top of the device was easily repaired using PVC cement and it passed all continuity tests. It is back in place and working FB.

2.4GHz won't work. It doesn't take much dirt or water to block a wi-fi signal.

Besides 457Khz avalanche locators, look into Ground Penetrating Radar. Most operate in the microwave region, but a few models work on very low frequencies 50-500KHz. FCC Part 19 has a list of acceptable frequency ranges. If you're tracking gophers, I vaguely recall seeing an article that described the technology (but am too busy to go Googling right now).

>the electrons can not do it either.  there are not enough of them and
they move too slowly in the plasma to propagate light.  these are
easily measured, you can watch the density directly using the ace
satellite web page and calculate the speed of longitudinal waves if
you want, but it won't be anywhere near light speed.

In wire are the sound waves (molecules vibrations) and the electric waves
(electrons vibrations).
The same is in space. There are the acoustic waves and electric waves.

Everybody measure the acoustic. The light (electric waves) speed is known.

 If light exsists than there is enough electrons.
Do not tell me that there is the Maxwell material:

"space that is devoid of electrons" is only in schools.
In space "About 99% of the interstellar medium is gas with about 90% of it
in the form of hydrogen (atomic or molecular form), 10% helium, and traces
of other elements" From: http://www.astronomynotes.com/ismnotes/s3.htm

Some elements are ionized. So there are the electrons.

That's funny :)

It would be for plotting tunnels from gopher, rabbits, etc. But I don't want to buy COTS, I want to grab all the components myself, put the circuits together on a few breadboards and make my own casing for it.

What's important is finding the simple components needed to implement this type of operation. I've read into ELTs and MELs (Miner Emergency Locator) as well, and while I have found a few circuit diagrams, they did not show what antenna is being used and/or how that was connected to the circuit.

Here is a good example. If I use this oscillator:
http://yhst-27389313707334.stores.yahoo.net/i2c1kto68pro.html
(Voltage adjustable from 1KHz to 68MHz)

If we set this to work off of 1-5KHz:
A) How would I figure out what antenna is needed to send this signal through 10-20ft of dirt and concrete?
B) Where on a circuit would this antenna be attached? (directly connected to the oscillator and 9-12V with perhaps a resistor in-between?)

Your friend the 555 may be just what you need. I will oscillate up to
around half a megacycle and have harmonics from DC to daylight.

Jimmie

Good evening (here), to all. I envy most of you for being in Spring...
```

Cecil I think I understand the notion you have of interaction. It is
on the concept pointed by the word itself (even outside of our radio
context, as shown in your comment about C =3D A + B) where the
"differences" are laying.
"We" (1) seem to agree with what just explained K1TTT in his last
post. If we could resolve this concept I believe that there would be
fewer differences in the radio discussion. Would you be willing to
try?.
(1) Three or four that are not you, off course :>D

There are other sometimes semi-elusive and possubly tricking concept:
"interference", from my point of wiew this one is other possible
source of differences on our topic.
......
> the only reason you can see standing waves is because a measurement or ob=
servation makes them look like they are 'standing' when it is really the in=
teraction of two or more regular traveling waves.

If I do not bad understand your response to Cecil, In your sentence I
would change "interaction" by "manifestation". What do you think?

Side comment: I would say "the only reason we can see (1) 'anything '
of the outside world is by measurement or observation ".
Standing waves are no different in this respect to any other
"external" thing. :>)
(1) Mind vision.

Richard: OK to "representations". Do you think there are things
accesible (or "visible") to our intelect (objectivism) or all we have
are models of external world built by our minds with the help and
mediation of our biological and technical sensing/measurements
apparatus?
I insist in that because I think that two or more models could be
capable to "explain" observed phenomena and we could partially agree
on they instead dispute hard about the "right one" :>)
Metaphysical discussions about the "thing itself" was very strong and
sterile before Newton stop caring about the "whys" and decided dealts
with "howtos" :>). I think you were thinking about this when you
equalize "because"=3D"superstition". Am I right?
However, though causality is an epistemological issue, usually in the
macroscopic phenomena we accept "If A, then B" as a causal relation,
example: If a rock hits my feet I absolutelly think the pain is due to
the stone, not a simple acausal correlation. In this sense is it valid
to use "because the stone")? Thanks to all for your comments

73

Consider just how big the antenna might have to be at those frequencies.
300,000,000 divided by F in Hz = length in meters.
Using your 5Khz (300,000,000/5000) = 60,000 meters !

That's true. Okay -- I obviously would need a lower frequency to penetrate
ground; what would be a workable solution?

What if I took 10ft of antennae and just coiled it so it didn't take up so
much space?

Thanks for all the info!

Up here in Alaska, we used to use the SAT Balanced Antenna Tuners to feed 300 Ohm Twin-lead Dipoles, cut for the Lowest Frequency Channel in the Radio. then use a Bird WattMeter in the Coax Feeding the Tuner, while doing the Setup. After things were setup for each channel and Band in the Radio, we would tape a pair of NE2's, one on each side of the Twin-lead at the closest Voltage Node to the Tuner. then the Operator could watch the RF Output on the NE2's. worked fair... for the those days...

no, it is not obvious. where do you draw the line... 1 degree, .1 degree, .001 degree? at what point is the angle small enough to say that they have 'interacted' and the energy is redistributed?

>
> Did superposition occur in both cases? Yes. Did interference occur in

>

i propose that 'cancellation' is just a special case of interference where the waves are 'close enough' to collinear that you never see the interference pattern. this would of course always apply in a transmission line because they are confined.

closely analyze the transient response of your non-reflective glass in the case where the wave is not incident perpendicular to the glass. do each reflection from each interface separately as the wave travels in the coating at an angle. then reduce the angle to very near perpendicular and you should see that there are indeed reflections that should very nearly 'cancel' each other out as the number of reflections gets bigger.

Andy writes: I messed with a transmitter used to map out caves and
tunnels a while back and think that would fit your bill. I don't
remember the details
but I think it ran around 100 Khz or so, and the antenna was just a
coil
of wire about a foot in diameter, using magnetic near field coupling.
Power was only a few watts and the range was hundreds of feet.

   If you google things like "cave mapping" , " spelunking
transmitters",

and keywords like that, you may have a lead to follow.

Good luck,

Andy W4OAH

Hi Miguel,

This has gotten pretty metaphysical.

>I insist in that because I think that two or more models could be
>capable to "explain" observed phenomena and we could partially agree
>on they instead dispute hard about the "right one" :>)

Data explains - the rest is the ego of pride of authorship.

Don't you think your pain is due to nerve sensations? Rocks hit rocks
all the time and there is no pain due to anything any where.

Or maybe there is an optical proof that refutes this.

Shucks, up there in Alaska, KL7BFB ("Barrel Full of Beer") ran a
(Alaska?) gallon of AM to a lazy H antenna. It had a fluorescent tube
taped to each of the four wire ends, which lit up nicely when he hit the
mike button. Ah, those were the days. . .

'Course I used to run out onto the runway at the Juneau airport to
retrieve ducks I'd shot. Bet you can't do that any more!

I don't remember writing that, Miguel. If I did write that, then I
misused the word "interaction". I wrote elsewhere that forward and
reflected waves don't interact as long as Z0 stays constant.

I don't know the answer but zero degrees (perfect collimation) will
result in interaction.

> i propose that 'cancellation' is just a special case of interference
> where the waves are 'close enough' to collinear that you never see the
> interference pattern.

When b1 =3D s11*a1 + s12*a2 =3D 0 at an impedance discontinuity, wave
cancellation has taken place. s11*a1 and s12*a2 are coherent sine
waves, equal in magnitude, and 180 degrees out of phase. Have you read
the FSU web page where they describe wave cancellation? All these
concepts are old hat to optical physicists.

micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/
waveinteractions/index.html

"... when two waves of equal amplitude and wavelength that are 180-
degrees ... out of phase with each other meet, they are not actually
annihilated, ... All of the photon energy present in these waves must
somehow be recovered or redistributed in a new direction, according to
the law of energy conservation ... Instead, upon meeting, the photons
are redistributed to regions that permit constructive interference, so
the effect should be considered as a redistribution of light waves and
photon energy rather than the spontaneous construction or destruction
of light."

Nope, you sure can't..... Years ago I was servicing an Alascom Alaska
Public Fixed Transmitter in Bethel that ran a Full Gallon on 2, 3, 5, &
8 MHz. The Operator I knew from a few years earlier, also was a Ham, and
was using one of the OLD Rhombics, From the WWII days, to work the West
Coast with 2 watts from a Northern Radio SSB Handheld Prototype on 40
meters. He was said to have the strongest Signal on the band as the sun
set each night. They just don't make antennas like those anymore.

At 457KHz they use ferrite rod antennas

I think if you are building your own system you need a crystal locked
transmitter and a very narrow bandwidth ( DSP filters ? ) receiver in
order to obtain the best range and rejection of unwanted noise and out
of band signals.

Some design notes can be found here.

http://www.ece.uvic.ca/~mblarows/ELEC499/documents/ELEC499A%20Progress%20Re=
port%202-r1.pdf

http://www.backcountryaccess.com/english/research/documents/457andFuture_00=
0.pdf

Google or search US patent websites for 457KHZ transmitter antenna.

> That's true. Okay -- I obviously would need a lower frequency

Lower frequencies mean longer antenna. :-(
Also since 5Khz is in the audio range of frequencies you might be better
off with a coil based microphone.

> to penetrate ground; what would be a workable solution?

I think you need to do some more research. Its easier not to re-invent
the wheel.

> What if I took 10ft of antennae and just coiled it so it didn't take
> up so much space?

If you take any antenna and reduce its physical size you will also
reduce the amount of energy that it can radiate for any given input. I
forget the rule of thumb, but it goes something like inverse square.
Half the radiation quarter of the distance.

I suggest that you immediately dump any reference that includes
a phrase like "photon energy present in a wave".

There is a wave theory of light, and there is a particle theory
of light, and these two theories do not play well together.

While in many situations they will yield the same answers, it
is not permissible to mix the concepts from each. Distrust
the conclusions of any exposition which does so.

agreed. photons are good when working with other elementary particle interactions to represent the em energy lost or transferred during particle interactions. they are not that useful when studying wave propagation or interaction with macroscopic object... including 1/4 wave coatings.

There seems to be some confusion about the meaning of resistance in these posts.

At the start of my electronics education (and I suspect most of yours), I was taught that resistance was:
R =3D V/I

This works for resistors, which have a linear V-I curve which passes through the origin. This R has the property that it can be used in R*I^2 to compute the power dissipated in the resistor.

Later in my training, a more sophisticated definition of resistance was introduced:
R =3D deltaV/deltaI
where the V-I curve is not a straight line or does not pass through the origin (and some devices even have a negative resistance).
With this, more sophisticated definition of resistance, it is often not correct to use R in R*I^2 to compute the dissipation.

It is always correct to compute the dissipation by multiplying the voltage by the corresponding current at a particular point on the V-I curve but V/I at this point is not the resistance unless the V-I curve is straight and passes throught the origin.

The plate V-I characteristic curves for a tube are quite non-linear and the use of plate resistance (i.e. deltaV/deltaI) for the computation of power is an invalid operation.

V*I of V and I selected at any point on the curve will yield the power, but V/I will not be the resistance at this point. You need to dV/dI for that.

...Keith

For those who may be interested, Richard Feynman offers an
introductory
lecture on photons here:  http://vega.org.uk/video/subseries/8

It illustrates that attempting to compute 1/4 wave coating behaviour
with photons would be extremely tedious, though possible.

On the other hand, at low light levels, where individual photons
become
discrete events, the wave theory becomes completely inadequate.
Fortunately, for practical applications, power levels are much higher
than this and the wave aproach is quite useful.

If you (and others) will give up on the ridiculous concept of EM wave energy standing still in standing waves, I will not have to refer to photons again. Honor the technical fact that EM forward waves (with an associated ExH energy) and EM reflected waves (with an associated ExH energy) are always present when standing waves are present and that those underlying waves (that cannot exist without energy) are moving at the speed of light in the medium back and forth between impedance discontinuities. Standing waves are somewhat of an illusion and according to two of my reference books, do not deserve to be called waves at all because standing waves do not transfer net energy as required by the definition of "wave". In short, it is impossible for EM waves to stand still.

Quoting one of my college textbooks, "Electrical Communication", by Albert:

"Such a plot of voltage is usually referred to as a *voltage standing wave* or as a *stationary wave*. Neither of these terms is particularly descriptive of the phenomenon. A plot of effective values of voltage, appearing as in Fig. 6(e), *is not a wave* in the usual sense. However, the term "standing wave" is in widespread use."

From "College Physics", by Bueche and Hecht:

"These ... patterns are called *standing waves*, as compared to the propagating waves considered above. They might better not be called waves at all, since they do not transport energy and momentum."

Technically, RF waves *are* light waves, just not *visible* light waves. All the laws of physics that govern EM waves of light also apply to RF waves. That you find it inconvenient for your "mashed-potatoes" theory of energy arguments is not a good reason to abandon the photonic nature of EM waves. It is actually a good reason to keep it in mind and abandon the mashed-potatoes energy arguments as human conceptual constructs that cannot exist in reality. Most of the energy in an EM wave is kinetic energy. Therefore, it cannot stand still.

> There is a wave theory of light, and there is a particle theory
> of light, and these two theories do not play well together.

If they are both correct, they should play well together. If there is any conflict, quantum electrodynamics wins the argument every time.

> While in many situations they will yield the same answers, it
> is not permissible to mix the concepts from each. Distrust
> the conclusions of any exposition which does so.

Actually, distrust the wave theory if it disagrees with QED. Quantum ElectroDynamics has never been proven wrong.

So feel free to prove that standing waves can exist without the underlying component traveling waves traveling at the speed of light in the medium. Feel free to prove that EM wave cancellation does not "redistribute energy to areas that permit constructive interference" as the FSU web page explains. Feel free to prove the Melles-Groit web page wrong when they say such has been proven experimentally. In fact, the interferometer experiment described here proves that reflected EM waves, traveling at the speed of light, exist along with the necessary energy. Take a look at the "non-standard output to screen".

http://www.teachspin.com/instruments/moderni/experiments.shtml

I, personally, am not interested in getting the right answer using the wrong concepts. And I am absolutely sure that your math models do not dictate reality. It is supposed to be the exact opposite.

Typo/Brain-fart -- I meant "higher" frequency

> I think you need to do some more research. Its easier not to re-invent
> the wheel.

I certainly do not wish to reinvent the wheel, but, I would like to carve and sand my own wheel, though -- for commercial reasons.

I'm looking for the most lowest level of development that one could start with given a humble work environment.

The impossibility of divergence. That collapsed probability function can occur in an RF transmission line and in an interferometer. Secondary effects, e.g. noise, are obviously ignored.

> coming from a 'primer' and containing words like 'somehow' doesn't
> raise my confidence in the explanation.

The "somehow" means that even if someone doesn't comprehend enough to have "confidence in the explanation", that lack of confidence will have zero effect on the real-world outcome - the energy involved in destructive interference wave cancellation will be preserved through constructive interference based on the conservation of energy principle. Please feel free to prove them wrong.

Photons are useful for proving that EM waves must necessarily travel
at the speed of light in the medium. Photons cannot stand still -
therefore, EM waves, known to consist of photons, cannot stand still -
therefore any overly-simplified mashed-potatoes version of energy
stored in an RF transmission line violates the laws of physics.

Hi Keith,

You want to try that again with actual data?

Start with Walt's:
>2 Finals 6146B
>
>In this condition the DC plate voltage is 800 v and plate current is 260 ma. DC
input power is therefore 800�V�0.26�A = 208�W.

I've no problem with that ! But you do need to look at what work has
already been done by other people and try to understand what problems
they have had to overcome in order to achieve their goal. Then analyse
what you need to do to achieve your goal.

>
> I'm looking for the most lowest level of development that one could

Most entrepreneurs start of with an idea and develop it with very little
resources. But you have to ask the right questions and more important
understand the answers.

Radio propagation through the earth is one of the most challenging
problems you could attempt to solve. You seem to be concentrating on
very low frequencies, fine if you can tolerate very very slow data
flows. I'm sure there are frequencies that will propagate through the
earth fairly easily, but getting to a point where a usable signal
occurs with reliable results isn't easy.

Maybe more information about what you are trying to achieve would help
to point you in a better direction.

Not a loaded question: How do Maxwell's equations applied to a
standing wave prove that the component forward and reflected waves are
moving at the speed of light in the medium? If it can and if I can
understand it, I wouldn't need to use the photon argument.

easy, maxwell's equations don't predict standing waves!  they are a
product of  superposition and the simplest instrumentation used since
they were first discovered.

Please correct me if I am wrong: If one starts with the (superposed) standing wave equation, V(x,t) =3D A*sin(kx)*sin(wt), Maxwell's equations seem to provide a perfectly valid result (not that I can recognize perfection). Therefore, how do Maxwell's equations prove that the component traveling waves necessarily possess a separate existence? Again, a serious question from an engineer who considers anything except a logical '0' or logical '1' to be broken. :-)

my differential calculus is a bit rusty, but i don't think that equation satisfies the basic wave equation. from Fields and Waves in Communication Electronics, section 1.14. a solution for the wave equation in a transmission line (or other 1d form) must satisfy the condition that the 2nd derivative wrt x and wrt t equal v-squared... too hard to write in text. but basically take the above and differentiate twice wrt time and twice wrt distance and i don't think you'll get anything that comes out to the velocity squared. the problem is that t and x must be part of the same sinusoid in the F(t-x/v) so that the wave is truly traveling instead of stationary like your equation provides.

in the basic maxwell equations in differential form you also run into the same problem where the curl of the one field is proportional to the time derivative of the other i think you'll end up with a contradiction like k=3Dw if you eliminate the dimensionless terms... i may be wrong on that because its been so long since i've had to deal with them on that level.

That's not true. All the power delivered to an antenna is either radiated or turned into heat -- antennas have to obey the law of conservation of energy like everything else. The fraction which is turned into heat is determined by the loss of the antenna, not its physical size. Loss does generally increase as the size gets smaller, but not by any fixed proportion to the size, and many small antennas can be quite efficient.

Oh!, I surrender  :>) The thread do not converge to a solution, it
seems run out toward a naked singularity!  I stay tuned until this
good brainstorm calms down ..

On the other hand an EM  antenna may not best suit  your job. I would
suggest feeding a buried coil and let this be half of a transformer
coupled to your receiver.

It might be worth checking out some of the work done by Bonnie Crystal
KQ6XA and her cohorts.  They've been able to communicate from the
earth's surface, down into caves (and back up), using LF and HF radio
systems.

I'm sure there are frequencies that will propagate through the earth fairly easily, but getting to a point where a usable signal occurs with reliable results isn't easy.
> . . .

Attenuation through the ground depends on the soil conductivity and dielectric constant, and the frequency. Here's the attenuation in dB/ft for two ground types and a number of frequencies:

Freq MHz	Avg soil(1)	Vy good soil(2)
0.01	0.037	0.091
0.1	0.12	0.29
1	0.35	0.90
10	0.66	2.4
100	0.69	3.3
10,000	0.69	3.4

(1) Conductivity = 0.005 S/m, dielectric constant = 13
(2) Conductivity = 0.03 S/m, dielectric constant = 20

So the distance you can communicate depends on these factors as well as antenna efficiency, power, and receiver sensitivity.

Attenuation in salt water is very much higher, which is why submerged submarines have to communicate at VLF.

So if I get this right, a 2.4gHz signal in normal soil would be anttenuated 6.9 db (less than 2 "S units). In very good soil, it would be anttenuated around 34 db, which would make it difficult to receive.

A Pringles can antenna has a gain of about 18db, that would certainly be enough for average soil, and might be good enough for very good soil.

It also has the advantage of possibly being a 2 way link.

Geoff.

Somewhat orthogonal to the previous post, but reasonable definitions.

> I believe that Walt has specified his definition.

Agreed.

Those dB values are correct for 10 feet of homogeneous soil. Real soil
is stratified, and reflections from layer boundaries could have some
pretty profound effects. 6.9 dB is from 2 to 4 "S-Units" on my Icom,
depending on where on the S meter scale it is.

> A Pringles can antenna has a gain of about 18db, that would certainly be
> enough for average soil, and might be good enough for very good soil.

Relative to what? According to this site
http://www.turnpoint.net/wireless/has.html, a Pringles can antenna
showed about the same gain as a Lucent omnidirectional antenna. Of
course, an 18 dB error is only a mis-estimation of power density by a
factor of 1,000,000,000,000,000,000. Pah, piddly nit-picking details.
You could make it up by increasing the power by the same factor.
```

> It also has the advantage of possibly being a 2 way link.

A reliable one would take some calculation, planning, and a realistic
idea of antenna performance.

Roy Lewallen, W7EL

>

Yup. Measure 800V at 0.26A and the power is 208 W. No mention of
resistance. This is good.

From Walt's data indicating 100W and the schematic showing a 5 ohm
cathode resistor, one
might infer that each tube is dissipating (208-100-(5*.26))/2->53.35
W. Feel free to include
the heater and grid dissipations for a more accurate evaluation.

From the 8146B spec sheet, depending on the operating point, Rp (i.e.
slope of plate E-I curve)
is between 10k and 30k so for the two tubes in the circuit it would be
5k to 15k ohms. But this
number is not much use for computing dissipations.

for subsurface comms and this sort of application, you typically use a
loop antenna, and accept the terrible efficiency of a physically small
antenna.

Look at the radios used by cavers for communication.

Refering to photons is just fine. Just do not mix them in with wave
theory.

All quite orthogonal to the original point, but your point about standing waves is quite correct, they are not really waves at all. But your need for the reality of underlying waves is quite excessive. The voltage and current distribution on a transmission line can be solved with a set of differential equations which satisfy some boundary conditions. There is no mention of forward and reverse waves in this solution. Turns out though, that the solution can also be factored in to a forward and reflected wave and this technique will provide the same answer. It does not make these waves any more real.

I bring you back to a previous question which you have never answered...
On an ideal line with 100% reflection, there are points where the current and voltage is always 0. Knowing that if either current or voltage is 0, power is also 0, how does energy cross these point?

And if I cut the line at all the places where the current is zero, it does not alter the energy distribution on the line one iota. How can this be if energy is travelling from end to end on the line?

> Technically, RF waves *are* light waves, just not *visible* light
> waves. All the laws of physics that govern EM waves of light also
> apply to RF waves.

PHYSICS has long given up on the idea of waves being an explanation for light. The wave theory fails miserably when illumination levels drop to the level that individual photons are being detected.

Though of course the earlier approximate models (waves) are still useful when intensity is high enough, just as we still use Newtonian mechanics to solve many every-day problems.

You might like to try http://vega.org.uk/video/subseries/8 for an exposition on the strangeness of photon.

> That you find it inconvenient for your "mashed-
> potatoes" theory of energy arguments is not a good reason to abandon
> the photonic nature of EM waves.

There you go again... mixing up you models. EM waves are analog and in
no way encompass the quantum nature of photons.

> It is actually a good reason to keep
> it in mind and abandon the mashed-potatoes energy arguments as human
> conceptual constructs that cannot exist in reality. Most of the energy
> in an EM wave is kinetic energy. Therefore, it cannot stand still.

There seems to be some misapprehension here. No one has claimed that
EM
waves stand still, though you may have been confused by the word
'standing' in 'standing waves'. But then earlier in your post you
quote
'College Physics' about 'standing waves', so it is not clear where
your confusion originates.

> > There is a wave theory of light, and there is a particle theory
> > of light, and these two theories do not play well together.
>

They are not both correct. QED aligns with many more observations than
does the wave theory. Another reason not to mix them.

> > While in many situations they will yield the same answers, it
> > is not permissible to mix the concepts from each. Distrust
> > the conclusions of any exposition which does so.
>

And the wave theory does disagree with QED at low levels, while at
higher illumination levels QED agrees with the wave theory.

And yet known of this aligns with the photons being part of the wave
theory of light. They two theories remain distinct.

Well, (and I am sorry, I can not resist), there is some evidence to
the
contrary. See:
   http://www.w5dxp.com/energy.htm
   http://www.w5dxp.com/nointfr.htm

...Keith

For all involved in the thread -- here's a perfect example. Sondes are
locator systems used in many areas (I think) such as pipelines:
http://www.rjmcompany.com/Pipe-cable-locator-RD2000-SuperCAT.htm

These have frequencies of 512hz, 8Khz and 33Khz

I'm searching for any specs now regarding crystal and antenna for both
transmitter and receiver. But I'm certain that the antenna isn't 1000's of
meters long ;)

If I'm reading this right -- I would want to build my own version of the
technology rather than purchase theirs'.

I have an old '58 copy of the ARRL handbook, and page 534 has the
"Twin-Lamp" tuning indicator for balanced line. It consists of a
couple of low-voltage flashlight bulbs wired to a short piece of
balanced line to insert into the transmission line.

Solder the tips of two flashlight bulbs together, wire that tip joint
to the short length of balanced line, and wire the bulb shells to the
line, too. Insert the device into the transmission line for tuning.

Fire things up. For minimum SWR, the bulb nearest the transmitter will
be bright, the bulb nearest the antenna will be dark. Or if the two
bulbs are glowing with the same brilliance, you have high SWR.

I am not interested in voltage and current. Like optical physicists, I
am only interested in tracking the RF energy flow.

> It does not make these waves any more real.

Agreed, but the point is that it does not make the traveling waves any
LESS real!

> power is also 0, how does energy cross these point?

Good grief, I have answered that question at least a dozen times. The net current being zero is just an illusion caused by superposition of two magnetic fields propagating in opposite directions that are equal in magnitude and opposite in phase. The two traveling waves keep on trucking at their relatively constant ExH energy levels in opposite directions. If you want to account for the energy, when the current is zero, all of the energy existing at that point is in the electric field and, sure enough, the voltage is at a maximum at that point- duuuhhhh again. There is absolutely no point on an active transmission line where the net energy level is zero. Again, you guys are never going to convince anyone that the Golden Gate Bridge doesn't need maintenance because the net traffic on the bridge is zero. How the heck can thousands of vehicles traveling one direction while the same number of vehicles are traveling in the opposite direction add up to zero effect in reality? Please get real.

> And if I cut the line at all the places where the current is zero, it
> does not alter the energy distribution on the line one iota. How can
> this be if energy is travelling from end to end on the line?

As I told you years ago, when you cut the line, you radically change the impedance and create a reflection that didn't exist before you cut the line. Hint: There are no reflections at a point of constant Z0. There are only reflections at an impedance discontinuity. The alteration of the energy distribution (to which you seem to be blind) can easily be observed in a TV system.

> PHYSICS has long given up on the idea of waves being an explanation
> for light.

And RF waves are technically light, just not visible light. When I was rummaging through the Texas A&M library, I found a book entitled, "Light". It covered the subject of RF waves.

> EM waves are analog and in
> no way encompass the quantum nature of photons.

You could become famous if you can prove that EM waves are not quantized. Good luck on that one.

> No one has claimed that EM waves stand still, ...

Please prove your ridiculous assertion that no one has ever claimed that EM waves can stand still.

While that is true your exiting installation may be better than you
think. Best Antenna can be subject to to any number of parameters
from greatest gain to practical operations and installation to
significant others opinion of aesthetic appeal.

Jimmie

definately. another simple condition shows this can't be correct
since current nodes correspond with voltage peaks in the standing wave
pattern, so while energy in the magnetic field is a minimum the energy
in the electric field is a maximum.

> 73, Cecil, w5dxp.com

this becomes MUCH harder to analyze. the transmission line case is
easy because the equations collapse to a single linear dimension, so
you can write your simple standing wave equation with a single sin(kx)
term. in a solenoid, especially a finite length solenoid, and double
especially because the length may be an appreciable fraction of a
wavelength, there is no such simple representation for the fields.
i'm not even sure what software would provide an adequate model of
something like that... the turns are too close for me to trust nec
based programs with out lots more research, and i'm pretty sure finite
element programs like ansoft/maxwell would not be able to handle the
change in current due to length and radiation. measurement of the
currents in coils like that would also be hard because of the radiated
fields and the shielding needed to prevent measurement errors from
probe lengths in the field... i would only trust fiber optic sensed
probes that were small and self contained, at least that way you would
not be distorting the field with probes or trying to cancel out pickup
from probe cables coupling to the antenna.

> Mobile mounted whip antennas fare even worse relative to simple textbook models. I don't have any experience with comparison of computer models with actual measurement. Those results should depend on the care with which the model is constructed and the amount of influence the ground has on the impedance.

I would figure that getting an accurate ground influence in an antenna design program would have to be a daunting project, indeed.

While installing my bugcatcher, I did a lot of it in stages, noting the positive influence on the results. My thinking at this point is that the make and model, and the size of the vehicle would be critical for the model, and small changes go a long way.

What's more, the more efficient and narrow the antenna, the more effect the changes have. Given that a good setup always involves a lot of custom work like bonding and turning potential radiators like the exhaust system into more bonded area, it is a really tough exercise.

As a point of clarification, Cecil, the bottom loaded bug catcher you
refer to - is it the matching coil or the loading coil? I only knew of
mid-loaded bugcatchers.

> and perhaps 30mA plate current. =A0That's effectively 2500 ohms to each plate of the pair. =A0But at that operating point, the plate resistance of a 6146 is around 600V/30mA, or 20k ohms (roughly, from plate characteristic curves in my old RCA transmitting tubes manual). =A0On the other hand, a triode will have a much lower plate resistance, likely similar to the load resistance--but again, not really related to it.
>
> Another rather interesting thing happens, though, when you connect an RF load through a tank circuit such as a PI network. =A0It's quite possible for a pi network to transform a 50 ohm RF load so it presents a reasonable (say) 4k ohm RF load to the plate of a tube like a 6146. But that same pi network will in turn transform the plate resistance--or rather, the net impedance of the tube in its particular circuit configuration (grounded grid or grounded cathode, and invariable some amount of feedback whether you wanted it or not), along with the DC feed (RF choke) in parallel, to quite possibly an impedance not very close to 50 ohms, and likely rather reactive. =A0I can, without much difficulty, design a PI network that will yield a source resistance at the output connector that's a lot less than 50 ohms, using a tetrode amplifier tube, while giving a very decent transformation of a 50 ohm load to a desired load at the plate of the tube.
>
> And as if that weren't enough, I can modify the output impedance further by application of feedback; this is more commonly done at audio frequencies, where amplifiers designed to drive loads like 4 ohms an 8 ohms have output impedances in the area of a small fraction of an ohm. =A0But it's also done with RF amplifiers, often for reasons unrelated to the output impedance, but also to control the output impedance so that it IS very close to 50 ohms (for example in instrumentation, where it may be important).
>
> Cheers,
> Tom

I'm going to break with my earlier decision to no longer respond to this thread in order to respond to Tom, K7ITM.

Tom, as you can see from my earlier posts I agree with your assessment of plate resistance, Rp, in that it is the partial derivative of the Ep/Ip relationship. Therefore, while Rp is definitely a factor in determining the value of load resistance RL, it is by no means the total source resistance of the RF power amplifier, as others insist.

I'm going to break with my earlier decision to no longer respond to
this thread in order to respond to Tom, K7ITM.

Tom, if you review my earlier posts, you'll find that I agree with you
concerning plate resistance Rp as the partial derivative of the Ep/Ip
relationship when both the grid and screen voltages are held constant.
Although Rp is definitely a factor in determining the value of load
resistance RL, it is by no means the total source resistance RL, as
others have insisted.

You can use any Insulated wire, Plastic Insulated or Enameled..... Most
use a very thin enameled 22 Gauge or smaller, and may even be wound on a
Ferrite Core to increase the Impedance...

Hello and good day all:

I believe perhaps I am not translating/understanding well your posts, Cecil and David, I post some comments to your consideration.

As I learnt, basic electromagnetic energy propagation Maxwell equations are satisfied by a traveling wave moving in one direction. Also I learnt standing waves in a TL results of two of them traveling in opposite directions (as I understand this is not a questioned point in this newsgroup), but SW equation it is not a Maxwell eq. solution but a mathematical result of interference among them. For that reason directly replacing this one in electroamagnetic energy propagation Maxwell diff. eqs to satisfy it, do not work, because SW do not travel anywhere!.
Energy not flowing beyond nodes it is a true, but only for ending nodes!
Could this be what confuses those who think energy do not cross INTERNAL TL nodes?

Electromagnetic waves are energy transport phenomenom, SWs not. We can interpret last ones as a "result of the transport phenomenom" (interference) =3D> Energy is "trapped" in a resonant ideal line, as is "trapped" in a resonant ideal cavity, as light ii is "trapped" in a optical ideal cavity.

Do we see a simple case: If we think in a half wave resonant line we can interpret/describe its internal state as two traveling waves (inside system transport) or with a standing wave dynamic interchange of energy between E and H field without radiation (not transport). In longer line it is the same: we can describe its internal state a two waves traveling between end boundaries (transport) or a sistem (line) located [but not f(x)] energy interchange among magnetic and electric field. (I said not f(x), because nodes and antinodes are "FIELDS (E and H) nodes and antinodes", but not "ENERGY nodes or antinodes" (as

we know, where H is 0, E is maximun...)
Seems to me this does not violate any quantum or clasic laws :>)

Jim, k7jeb, once used a standard 75m Texas Bugcatcher coil as a base-loaded whip (no top hat) and entered one of the CA 75m mobile shootouts. He was "only" 3 dB down from similar center-loaded Texas Bugcatchers (no top hat). This fits well with the radiation resistance estimate for the center-loaded bugcatcher being double that of the base-loaded configuration.

Well maybe it is much harder using Maxwell's equations but maybe there is a simple representation. See what you think about this idea. At the following web site is an impedance calculator that will yield the characteristic impedance and velocity factor of a loading coil so the coil can be analyzed the same way as a transmission line. (We also can model the whip using EZNEC and, like a transmission line stub, equate the feedpoint impedance to the impedance of a lossy open-circuit stub.) We know the Z0 of the whip will be a few hundred ohms.

http://hamwaves.com/antennas/inductance.html

The velocity factor of the specified coil can be calculated from the axial propagation factor in radians per meter.

So please assume a frequency of 4 MHz and a typical six inch long bugcatcher loading coil with a Z0 of 3800 ohms and a VF of 0.024. All losses in/from the coil can be lumped together as if they were normal transmission line losses. The electrical length of the coil can be calculated from the physical length and VF. I don't see that it is all that "MUCH harder to analyze" than a transmission line example with the same amount of losses.
